(a) XM designations in this column are ASTM designations for the listed alloy.

(b) Single values are maximum values unless otherwise indicated.

(c) Nominal compositions.

(d) UNS designation has not been specified. This designation appears in ASTM A 887 and merely indicates the form to be used.

A cooperative study of ASTM and SAE resulted in the Unified Numbering System (UNS) for designation and identification of metals and alloys in commercial use in the United States. In UNS listings, stainless steels are identified by the letter S, followed by five digits. A few stainless alloys are classified as nickel alloys in the UNS system (identification letter N) because of their high nickel and low iron (less than 50%) contents.

Use of UNS numbers and AISI standard-type numbers ensures that a consumer can obtain suitable material time after time even from different producers or suppliers. Nevertheless, some variation in fabrication and service characteristics can be expected, even with material obtained from a single producer.

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Factors in Selection

The first and most important step toward successful use of a stainless steel is selection of a type that is appropriate for the application. There are a large number of standard types that differ from one another in composition, corrosion resistance,

physical properties, and mechanical properties; selection of the optimum type for a specific application is the key to satisfactory performance at minimum total cost.

The characteristics and properties of individual types discussed in this article and elsewhere in this Volume provide some of the information useful in steel selection. For a more detailed discussion, the reader is referred to *Design Guidelines for the Selection and Use of Stainless Steel*, published by the Committee of Stainless Steel Producers and available through AISI.

A checklist of characteristics to be considered in selecting the proper type of stainless steel for a specific application includes:

- Corrosion resistance
- Resistance to oxidation and sulfidation
- Strength and ductility at ambient and service temperatures
- Suitability for intended fabrication techniques
- Suitability for intended cleaning procedures
- Stability of properties in service
- Toughness
- Resistance to abrasion and erosion
- Resistance to galling and seizing
- Surface finish and/or reflectivity
- Magnetic properties
- Thermal conductivity
- Electrical resistivity
- Sharpness (retention of cutting edge)
- Rigidity

Corrosion resistance is frequently the most important characteristic of a stainless steel, but often is also the most difficult to assess for a specific application. General corrosion resistance to pure chemical solutions is comparatively easy to determine, but actual environments are usually much more complex. Tables 4 and 5 show resistance of standard types to various common media.

Table 4 Resistance of standard types of stainless steel to various classes of environments

Table 5 Relative corrosion resistance of AISI stainless steels for different grade applications

Environment	Grades ^(a)
Acids	
Hydrochloric acid	Stainless is not generally recommended except when solutions are very dilute and at room temperature (pitting may occur).
Mixed acids	There is usually no appreciable attack on type 304 or 316 as long as sufficient nitric acid is present.
Nitric acid	Type 304L and 430 and some higher-alloy stainless grades have been used.
Phosphoric acid	Type 304 is satisfactory for storing cold phosphoric acid up to 85% and for handling concentrations up to 5% in some unit processes of manufacture. Type 316 is more resistant and is generally used for storing and manufacture if the fluorine content is not too high. Type 317 is somewhat more resistant than type 316. At concentrations $\leq 85\%$, the metal temperature should not exceed 100 °C (212 °F) with type 316 and slightly higher with type 317. Oxidizing ions inhibit attack.
Sulfuric acid	Type 304 can be used at room temperature for concentrations >80 to 90%. Type 316 can be used in contact with sulfuric acid $\leq 10\%$ at temperatures ≤ 50 °C (120 °F) if the solutions are aerated; the attack is greater in air-free solutions. Type 317 may be used at temperatures as high as 65 °C (150 °F) with $\leq 5\%$ concentration. The presence of other materials may markedly change the corrosion rate. As little as 500 to 2000 ppm of cupric ions make it possible to use type 304 in hot solutions of moderate concentration. Other additives may have the opposite effect.
Sulfurous acid	Type 304 may be subject to pitting, particularly if some sulfuric acid is present. Type 316 is usable at moderate concentrations and temperatures.
Bases	
Ammonium hydroxide, sodium hydroxide, caustic solutions	Steels in the 300 series generally have good corrosion resistance at virtually all concentrations and temperatures in weak bases, such as ammonium hydroxide. In stronger bases, such as sodium hydroxide, there may be some attack, cracking, or etching in more concentrated solutions and/or at higher temperatures. Commercial-purity caustic solutions may contain chlorides, which will accentuate any attack and may cause pitting of type 316, as well as type 304.
Organics	
Acetic acid	Acetic acid is seldom pure in chemical plants but generally includes numerous and varied minor constituents. Type 304 is used for a wide variety of equipment including stills, base heaters, holding tanks, heat exchangers, pipelines, valves, and pumps for concentrations $\leq 99\%$ at temperatures ≤ 50 °C (120 °F). Type 304 is also satisfactory--if small amounts of turbidity or color pickup can be tolerated--for room temperature storage of glacial acetic acid. Types 316 and 317 have the broadest range of usefulness, especially if formic acid is also present or if solutions are unaerated. Type 316 is used for fractionating equipment, for 30-99% concentrations where type 304 cannot be used, for storage vessels, pumps, and process equipment handling glacial acetic acid, which would be discolored

	by type 304. Type 316 is likewise applicable for parts having temperatures $>50^{\circ}\text{C}$ (120°F), for dilute vapors, and for high pressures. Type 317 has somewhat greater corrosion resistance than type 316 under severely corrosive conditions. None of the stainless steels has adequate corrosion resistance to glacial acetic acid at the boiling temperature or at superheated vapor temperatures.
Aldehydes	Type 304 is generally satisfactory.
Amines	Type 316 is usually preferred to type 304.
Cellulose acetate	Type 304 is satisfactory for low temperatures, but type 316 or type 317 is needed for high temperatures.
Formic acids	Type 304 is generally acceptable at moderate temperatures, but type 316 is resistant to all concentrations at temperatures up to boiling.
Esters	With regard to corrosion, esters are comparable to organic acids.
Fatty acids	Type 304 is resistant to fats and fatty acids $\leq \sim 150^{\circ}\text{C}$ (300°F), but type 316 is needed at $150\text{--}260^{\circ}\text{C}$ ($300\text{--}500^{\circ}\text{F}$), and type 317, at higher temperatures.
Paint vehicles	Type 316 may be needed if exact color and lack of contamination are important.
Phthalic anhydride	Type 316 is usually used for reactors, fractionating columns, traps, baffles, caps, and piping.
Soaps	Type 304 is used for parts such as spray towers, but type 316 may be preferred for spray nozzles and flake-drying belts to minimize off-color product.
Synthetic detergents	Type 316 is used for preheat, piping, pumps, and reactors in catalytic hydrogenation of fatty acids to give salts of sulfonated high-molecular alcohols.
Tall oil (pulp and paper industry)	Type 304 has only limited use in tall-oil distillation service. High rosin acid streams can be handled by type 316L with a minimum molybdenum content of 2.75%. Type 316 can also be used in the more corrosive high fatty acid streams at temperatures $\leq 245^{\circ}\text{C}$ (475°F), but type 317 will probably be required at higher temperatures.
Tar	Tar distillation equipment is almost all type 316 because coal tar has a high chloride content; type 304 does not have adequate resistance to pitting.
Urea	Type 316L is generally required.
Pharmaceuticals	Type 316 is usually selected for all parts in contact with the product because of its inherent corrosion resistance and greater assurance of product purity.

Source: Ref 3

- (a) The stainless steels mentioned may be considered for use in the indicated environments. Additional information or corrosion expertise may be necessary prior to use in some environments; for example, some impurities may cause localized corrosion (such as chlorides causing pitting or

stress-corrosion cracking of some grades).

General corrosion is often much less serious than localized forms such as stress-corrosion cracking, crevice corrosion in tight spaces or under deposits, pitting attack, and intergranular attack in sensitized material such as weld heat-affected zones (HAZ). Such localized corrosion can cause unexpected and sometimes catastrophic failure while most of the structure remains unaffected, and therefore must be considered carefully in the design and selection of the proper grade of stainless steel. Corrosive attack can also be increased dramatically by seemingly minor impurities in the medium that may be difficult to anticipate but that can have major effects, even when present in only parts-per-million concentrations; by heat transfer through the steel to or from the corrosive medium; by contact with dissimilar metallic materials; by stray electrical currents; and by many other subtle factors. At elevated temperatures, attack can be accelerated significantly by seemingly minor changes in atmosphere that affect scaling, sulfidation, or carburization.

Despite these complications, a suitable steel can be selected for most applications on the basis of experience, perhaps with assistance from the steel producer. Laboratory corrosion data can be misleading in predicting service performance. Even actual service data have limitations, because similar corrosive media may differ substantially because of slight variations in some of the corrosion factors listed above. For difficult applications, the extensive study of comparative data may be necessary, sometimes followed by pilot plant or in-service testing.

More detailed information is available in the section "Corrosion Properties" in this article.

Mechanical properties at service temperature are obviously important, but satisfactory performance at other temperatures must be considered also. Thus, a product for arctic service must have suitable properties at subzero temperatures even though steady-state operating temperature may be much higher; room-temperature properties after extended service at elevated temperature can be important for applications such as boilers and jet engines, which are intermittently shut down.

Fabrication and Cleaning. Frequently a particular stainless steel is chosen for a fabrication characteristic such as formability or weldability. Even a required or preferred cleaning procedure may dictate the selection of a specific type. For instance, a weldment that is to be cleaned in a medium such as nitric-hydrofluoric acid, which attacks sensitized stainless steel, should be produced from stabilized or low-carbon stainless steel even though sensitization may not affect performance under service conditions.

Experience in the use of stainless steels indicates that many factors can affect their corrosion resistance. Some of the more prominent factors are:

- Chemical composition of the corrosive medium, including impurities
- Physical state of the medium--liquid, gaseous, solid, or combinations thereof
- Temperature
- Temperature variations
- Aeration of the medium
- Oxygen content of the medium
- Bacteria content of the medium
- Ionization of the medium
- Repeated formation and collapse of bubbles in the medium
- Relative motion of the medium with respect to the steel
- Chemical composition of the metal
- Nature and distribution of microstructural constituents
- Continuity of exposure of the metal to the medium
- Surface condition of the metal
- Stresses in the metal during exposure to the medium
- Contact of the metal with one or more dissimilar metallic materials
- Stray electric currents
- Differences in electric potential
- Marine growths such as barnacles
- Sludge deposits on the metal

- Carbon deposits from heated organic compounds
- Dust on exposed surfaces
- Effects of welding, brazing, and soldering

Surface Finish. Other characteristics in the stainless steel selection checklist are vital for some specialized applications but of little concern for many applications. Among these characteristics, surface finish is important more often than any other except corrosion resistance. Stainless steels are sometimes selected because they are available in a variety of attractive finishes. Surface finish selection may be made on the basis of appearance, frictional characteristics, or sanitation. The effect of finish on sanitation sometimes is thought to be simpler than it actually is, and tests of several candidate finishes may be advisable. The selection of finish may in turn influence the selection of the alloy because of differences in availability or durability of the various finishes for different types. For example, a more corrosion-resistant stainless steel will maintain a bright finish in a corrosive environment that would dull a lower-alloy type. Selection among finishes is described in more detail in this article in the section "Surface Finishing of Stainless Steel."

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Product Forms

Stainless steels are available in the form of plate, sheet, strip, foil, bar, wire, semifinished products, pipes, tubes, and tubing.

Plate

Plate is a flat-rolled or forged product more than 250 mm (10 in.) in width and at least 4.76 mm (0.1875 in.) in thickness. Stainless steel plate is produced in most of the types shown in Table 2. Exceptions include highly alloyed ferritic stainless steels, some of the martensitic stainless steels, and a few of the free-machining grades. Plate is usually produced by hot rolling from slabs that have been directly cast or rolled from ingots and that usually have been conditioned to improve plate surface. Some plate may be produced by direct rolling from ingot. This plate is referred to as sheared plate or sheared mill plate when rolled between horizontal rolls and trimmed on all edges, and as universal plate or universal mill plate when rolled between horizontal and vertical rolls and trimmed only on the ends. Universal plate is sometimes rolled between grooved rolls.

Stainless steel plate is generally produced in the annealed condition and is either blast cleaned or pickled. Blast cleaning is generally followed by further cleaning in appropriate acids to remove surface contaminants such as particles of steel picked up from the mill rolls. Plate can be produced with mill edge and uncropped ends.

Sheet

Sheet is a flat-rolled product in coils or cut lengths at least 610 mm (24 in.) wide and less than 4.76 mm (0.1875 in.) thick. Stainless steel sheet is produced in nearly all types shown in Table 2 except the free-machining and certain martensitic grades. Sheet from the conventional grades is almost exclusively produced on continuous mills. Hand mill production is usually confined to alloys that cannot be produced economically on continuous mills, such as certain high-temperature alloys.

The steel is cast in ingots, and the ingots are rolled on a slabbing mill or a blooming mill into slabs or sheet bars. The slabs or sheet bars are then conditioned prior to being hot rolled on a finishing mill. Alternatively, the steel may be

continuous cast directly into slabs that are ready for hot rolling on a finishing mill. The current trend worldwide is toward greater production from continuous cast slabs.

Sheet produced from slabs on continuous rolling mills is coiled directly off the mill. After they are descaled, these hot bands are cold rolled to the required thickness, and coils off the cold mill are either annealed and descaled or bright annealed. Belt grinding to remove surface defects is frequently required at hot bands or at an intermediate stage of processing. Full coils or lengths cut from coils may then be lightly cold rolled on either dull or bright rolls to produce the required finish. Sheet may be shipped in coils, or cut sheets may be produced by shearing lengths from a coil and flattening them by roller leveling or stretcher leveling.

Sheet produced on hand mills from sheet bars is rolled in lengths and then annealed and descaled. It may be subjected to additional operations, including cold reduction, annealing, descaling, light cold rolling for finish, or flattening.

A specified minimum tensile strength, minimum yield strength, or hardness level higher than that normally obtained on sheet in the annealed condition, or a combination thereof, can be attained by controlled cold rolling.

Sheet made of chromium-nickel stainless steel (often type 301) or of chromium-nickel-manganese stainless steel (often type 201) is produced in the following cold-rolled tempers:

Strip

Strip is a flat-rolled product, in coils or cut lengths, less than 610 mm (24 in.) wide and 0.13 to 4.76 mm (0.005 to 0.1875 in.) thick. Cold finished material 0.13 mm (0.005 in.) thick and less than 610 mm (24 in.) wide fits the definitions of both strip and foil and may be referred to by either term.

Cold-rolled stainless steel strip is manufactured from hot-rolled, annealed, and pickled strip (or from slit sheet) by rolling between polished rolls. Depending on the desired thickness, various numbers of cold-rolling passes through the mill are required for effecting the necessary reduction and securing the desired surface characteristics and mechanical properties.

Hot-rolled stainless steel strip is a semifinished product obtained by hot-rolling slabs or billets and is produced for conversion to finished strip by cold rolling.

Heat Treatment. Strip of all types of stainless steel is usually either annealed or annealed and skin passed, depending on requirements. When severe forming, bending, and drawing operations are involved, it is recommended that such requirements be indicated so that the producer will have all the information necessary to ensure that he supplies the proper type and condition. When stretcher strains are objectionable in ferritic stainless steels such as type 430, they can be minimized by specifying a No. 2 finish. Cold-rolled strip in types 410, 414, 416, 420, 431, 440A, 440B, and 440C can be produced in the hardened and tempered condition.

Temper	Minimum tensile strength		Minimum yield strength	
	MPa	ksi	MPa	ksi
$\frac{1}{4}$ hard	860	125	515	75
$\frac{1}{2}$ hard	1035	150	760	110
$\frac{3}{4}$ hard	1205	175	930	135
Full hard	1275	185	965	140

Strip made of chromium-nickel stainless steel (often type 301) or of chromium-nickel-manganese stainless steel (often type 201) is produced in the same cold-rolled tempers in which sheet is produced.

For strip, edge condition is often important--more important than it usually is for sheet. Strip can be furnished with various edge specifications:

- Mill edge (as produced, condition unspecified)
- No. 1 edge (edge rolled, rounded, or square)
- No. 3 edge (as slit)
- No. 5 edge (square edge produced by rolling or filing after slitting)

Mill edge is the least expensive edge condition, and is adequate for many purposes. No. 1 edge provides improved width tolerance over mill edge plus a cold-rolled edge condition; rounded edges are preferred for applications requiring the lowest degree of stress concentration at corners. No. 3 and No. 5 edges give progressively better width tolerance and squareness over No. 1 edge.

Foil

Foil is a flat-rolled product, in coil form, up to 0.13 mm (0.005 in.) thick and less than 610 mm (24 in.) wide. Foil is produced in slit widths with edge conditions corresponding to No. 3 and No. 5 edge conditions for strip.

Foil is made from types 201, 202, 301, 302, 304, 304L, 305, 316, 316L, 321, 347, 430, and 442, as well as from certain proprietary alloys.

The finishes, tolerances, and mechanical properties of foil differ from those of strip because of limitations associated with the way in which foil is manufactured. Nomenclature for finishes, and for width and thickness tolerances, vary among producers.

Finishes for foil are described by the finishing operations employed in their manufacture. However, each finish in itself is a category of finishes, with variations in appearance and smoothness that depend on composition, thickness, and method of manufacture. Chromium-nickel and chromium-nickel-manganese stainless steels have a characteristic appearance different from that of straight chromium types for corresponding finish designations.

Mechanical Properties. In general, mechanical properties of foil vary with thickness. Tensile strength is increased somewhat, and ductility is lowered, by a decrease in thickness.

Bar

Bar is a product supplied in straight lengths; it is either hot or cold finished and is available in various shapes, sizes, and surface finishes. This category includes small shapes whose dimensions do not exceed 75 mm (3 in.) and, second, hot-rolled flat stock at least 3.2 mm (0.125 in.) thick and up to 250 mm (10 in.) wide.

Hot-finished bar is commonly produced by hot rolling, forging, or pressing ingots to blooms or billets of intermediate size, which are subsequently hot rolled, forged, or extruded to final dimensions. Whether rolling, forging, or extrusion is selected as the finishing method depends on several factors, including composition and final size.

Following hot rolling or forging, hot-finished bar may be subjected to various operations, including:

- Annealing or other heat treatment
- Descaling by pickling, blast cleaning, or other methods
- Surface conditioning by grinding or rough turning
- Machine straightening

Cold-finished bar is produced from hot-finished bar or rod by additional operations such as cold rolling or cold drawing, which result in the close control of dimensions, a smooth surface finish, and higher tensile and yield strengths. Sizes and shapes of cold reduced stock classified as bar are essentially the same as for hot-finished bar, except that all cold reduced flat stock less than 4.76 mm (0.1875 in.) thick and over 9.5 mm (0.375 in.) wide is classified as strip.

Cold-finished round bar is commonly machine straightened; afterward, it can be centerless ground or centerless ground and polished. Centerless grinding and polishing do not alter the mechanical properties of cold-finished bar and are used only to improve surface finish or provide closer tolerances. Some increase in hardness, more marked at the surface and particularly in 2xx and 3xx stainless steels, results from machine straightening. The amount of increase varies chiefly with composition, size, and amount of cold work necessary to straighten the bar.

Cold-finished bars that are square, flat, hexagonal, octagonal, or of certain special shapes are produced from hot-finished bars by cold drawing or cold rolling.

When cold-finished bar is required to have high strength and hardness, it is cold drawn or heat treated, depending on composition, section size, and required properties. Round sections can be subsequently centerless ground or centerless ground and polished.

Free-machining wire is a bar commodity used for making parts in automatic screw machines or other types of machining equipment. The principal types used are 303, 303Se, 416, 416Se, 420F, 430F, and 430FSe. Free-machining wire is commonly produced with a cold drawn or centerless ground finish and with selected hardnesses, depending on the machining operation involved.

Structural Shapes. Hot-rolled, bar-size structural shapes are produced in angles, channels, tees, and zees. They can be purchased in various conditions:

- Hot rolled
- Hot rolled and annealed
- Hot rolled, annealed, and blast cleaned
- Hot rolled, annealed, and chemically cleaned
- Hot rolled, annealed, blast cleaned, and chemically cleaned

Wire

Wire is a coiled product derived by cold finishing hot-rolled and annealed rod. Cold finishing imparts excellent dimensional accuracy, good surface smoothness, a fine finish, and specific mechanical properties. Wire is produced in several tempers and finishes.

Wire is customarily referred to as round wire when the contour is completely cylindrical and as shape wire when the contour is other than cylindrical. For example, wires that are half round, half oval, oval, square, rectangular, hexagonal, octagonal, or triangular in cross section are all referred to as shape wire. Shape wire is cold finished either by drawing or by a combination of drawing and rolling.

In the production of wire, rod (which is a coiled hot-rolled product approximately round in cross section) is drawn through the tapered hole of a die or a series of dies. The smallest size of hot-rolled rod commonly made is 5.5 mm (0.218 in.). Rod smaller than this is produced by cold work, the number of dies employed depending on the finished diameter required.

Round stainless steel wire is commonly produced within the approximate size range 0.08 to 15.9 mm (0.003 to 0.625 in.). Shape wire, except cold-finished flat wire, is commonly produced within the approximate size range of 1.12 to 12.7 mm (0.044 to 0.500 in.), although the particular shape governs the specific sizes that can be produced.

Tempers of Wire. There are four classifications of wire temper: annealed-temper, soft-temper, intermediate-temper, and spring-temper.

Annealed temper describes soft wire that has undergone no further cold drawing after the last annealing treatment. Wire in this temper is made by annealing in open-fired furnaces or molten salt, and annealing ordinarily is followed by pickling that produces a clean, gray, matte finish. It is also made with a bright finish by annealing in a protective atmosphere and sometimes is described as bright annealed wire.

Soft-temper wire is given a single light draft following the final annealing operation and generally is produced to a defined upper limit of tensile strength or hardness. Wire in this temper is produced with various dry-drawn finishes, including lime soap, lead, copper, and oxide. It may also be given a bright finish produced by oil or grease drawing.

Intermediate-temper wire is drawn one or more drafts after annealing as required to produce a specific minimum strength or hardness. The properties of this wire can vary between the properties of soft-temper wire and properties approaching those of spring-temper wire. Intermediate-temper wire is usually produced with one of the dry-drawn finishes.

Spring-temper wire is drawn several drafts as required to produce high tensile strengths.

Special Wire Commodities. There are many classes of stainless steel wire that have been developed for specific components or for particular applications. The unique properties of each of these individual wire commodities are developed by employing a particular combination of composition, steel quality, process heat treatment, and cold drawing practice. The details of manufacture may vary slightly from one wire manufacturer to another, but the finished wire will fulfill the specified requirements.

Cold-heading wire is produced in any of the various types of stainless steel. In all instances, cold-heading wire is subjected to special testing and inspection to ensure satisfactory performance in cold-heading and cold-forging operations.

Of the chromium-nickel group, types 305 and 302Cu are used for cold-heading wire and generally are necessary for severe upsetting. Other grades commonly cold formed include 304, 316, 321, 347, and 384.

Of the 4xx series, types 410, 420, 430, and 431 are used for a variety of cold-headed products. Types 430 and 410 are commonly used for severe upsetting and for recessed-head screws and bolts. Types 416, 416Se, 430F, and 430FSe are intended primarily for free cutting and are not recommended for cold heading.

Cold-heading wire is manufactured using a closely controlled annealing treatment that produces optimum softness and still permits a very light finishing draft after pickling. The purposes of the finishing draft are to provide a lubricating coating that will aid the cold-heading operation and to produce a kink-free wire coil having more uniform dimensions.

Cold-heading wire is produced with a variety of finishes, all of which have the function of providing proper lubrication in the header dies. The finish or coating should be suitably adherent to prevent galling and excessively rapid die wear. A copper coating, which is applied after the annealing treatment and just prior to the finishing draft, is available; the copper-coated wire is then lime coated and drawn, using soap as the drawing lubricant. Coatings of lime and soap or of oxide and soap are also employed.

Spring wire is drawn from annealed rod and is subjected to mill tests and inspection that ensures the quality required for extension and compression springs. The types of stainless steel of which spring wire is commonly produced include 302, 304, and, for additional corrosion resistance, 316, and UNS N08020.

Spring wire in large sizes can be furnished in a variety of finishes, such as dry-drawn lead, copper, lime and soap, and oxide and soap. Fine sizes are usually wet drawn, although they can be dry drawn.

Tensile strength ranges or minimums for types 302, 304, 305, and 316 spring wire in various sizes are given in Table 6.

Table 6 Room-temperature tensile strength of stainless steel spring wire

--------	--------	------------------

The torsional modulus for stainless steel spring wire may range from 59 to 76 GPa (8.5 to 11×10^6 psi), depending on alloy and wire size. Magnetic permeability is extremely low compared to that of carbon steel wire. Springs made from stainless steel wire retain their physical and mechanical properties at temperatures up to about 315 °C (600 °F).

Rope wire is used to make rope, cable, and cord for a variety of uses, such as aircraft control cable, marine rope, elevator cable, slings, and anchor cable. Because of special requirements for fatigue strength, rope wire is produced from specially selected and processed material.

Rope wire is made of type 302 or type 304 unless a higher level of corrosion resistance is required, in which case type 316 is generally selected. Special nonmagnetic characteristics may be required, which necessitate the selection of grades that have little or no ferrite or martensite in the microstructure and the use of special drawing practices to limit or avoid deformation-induced transformation to martensite.

Tensile properties of regular rope wire are slightly lower than those of stainless steel spring wire. Finishes for rope wire vary from a gray matte finish to a bright finish and include a series of bright to dark soap finishes. Soap finishes afford some lubrication that facilitates laying up of rope and also to some extent aids in-service use.

Weaving wire is used in the weaving of screens for many different applications in coal mines, sand-and-gravel pits, paper mills, chemical plants, dairy plants, oil refineries, and food-processing plants. Annealing and final drawing must be carefully controlled to maintain uniform temper and finish throughout each coil or spool. Because weaving wire must be ductile, it is usually furnished in the annealed temper with a bright annealed finish, or in the soft temper with either a lime-soap finish or an oil- or grease-drawn finish.

Most types of stainless steel are available in weaving wire; the most widely used types are 302, 304, 309, 310, 316, 410, and 430. Annealed wire in the 3xx series commonly has a tensile strength of 655 to 860 MPa (95 to 125 ksi) and an elongation (in 50 mm, or 2 in.) of 35 to 60%. Soft-temper wire, which is commonly specified for sizes over 0.75 mm (0.030 in.), averages 860 to 1035 MPa (125 to 150 ksi) in tensile strength and exhibits 15 to 40% elongation. For annealed wire in types 410 and 430, tensile strength averages 495 to 585 MPa (72 to 85 ksi), and elongation averages 17 to 23%.

Armature binding wire is produced in types 302 or 304 stainless steel of a composition that is balanced to produce high tensile and yield strengths and low magnetic permeability. Minimum tensile strength of 1515 MPa (220 ksi), minimum yield strength (0.2% offset) of 1170 MPa (170 ksi), and maximum permeability of 4.0 at 16 kA · m⁻¹ (200 oersteds) are usually specified. The wire must be strong enough to withstand the centrifugal forces encountered in use, yet ductile enough to withstand being bent sharply back on itself without cracking when a hook is formed to hold the armature wire during the binding operation. Armature binding wire is furnished on spools and has a smooth, tightly adherent tinned coating that facilitates soldering.

Slide forming wire is produced in all standard types, particularly in types 302, 304, 316, 410, and 430. It can be produced in any temper suitable for forming any of the numerous shapes made on slide-type wire forming machines.

Wool wire is designed for the production of wool by shredding. It is commonly furnished in an intermediate temper and produced to rigid standards so that it will perform satisfactorily in the wool-cutting operation. Wool wire usually is made from type 430 and has a lime-soap finish.

Reed wire is high-quality wire produced for the manufacture of dents for reeds that, once assembled, are used in weaving textiles and other products. Dents are made by rolling the round reed wire into a flat section, and then machining and polishing the edges to a very smooth and accurate contour before cutting the wire into individual dents. Accuracy in size and shape are necessary because of the various processes that the wire must undergo.

Reed wire is usually made from type 430 in an intermediate temper that must be uniform in properties throughout each coil and each shipment. The finish also must be uniform and bright.

Lashing wire is designed for lashing electric power transmission lines to support cables. Lashing wire is usually made from type 430. It is furnished in the annealed temper with a bright finish and has a maximum tensile strength of 655 MPa (95 ksi) and minimum elongation of 17% in 255 mm (10 in.). It is normally furnished on coreless spools.

Cotter pin wire is approximately half-round wire designed for fabricating cotter pins. It is generally produced by rolling round wire between power-driven rolls, by drawing it between power-driven rolls, or by drawing it through a die or Turk's-head roll. To facilitate the spreading of the cotter pin ends, it is desirable that the flat side of the wire have a small radius rather than sharp corners at the edges.

Cotter pin wire is commonly furnished in vibrated or hank-wound coils with the flat side of the wire facing inward. Ordinarily it is produced in the soft temper to prevent undesirable springback in the legs of formed cotter pins. Usually it is furnished with a bright finish, but it is also available with a metallic coating.

Stainless welding wire is available for many grades to provide good weldability with optimized mechanical properties and corrosion resistance of the weldment. For example, the weldability of austenitic stainless steels is enhanced by controlling unwanted residual elements or balancing the wire composition to provide a small amount of ferrite in the as-deposited weld metal. Also, the composition of duplex stainless weld wire is generally controlled to produce levels of austenite and ferrite in the weld metal that will optimize mechanical properties and corrosion resistance.

Stainless steel weld wire is produced in layer-level wound spools, straight lengths (both included in the American Welding Society AWS A5.9) and coated electrodes (AWS A5.4).

Semifinished Products

Blooms, billets, and slabs are hot rolled, hot forged, or hot pressed to approximate cross-sectional dimensions and generally have rounded corners. Round billets are also produced, typically for extrusion or closed-die forging. These semifinished products, as well as tube rounds, are produced in random lengths or are cut to specified lengths or to specified weights. There are no invariable criteria for distinguishing between the terms bloom and billet, and often they are used interchangeably.

Dimensions. The nominal cross-sectional dimensions of blooms, billets, and slabs are designated in inches and fractions of an inch. The size ranges commonly listed as hot-rolled stainless steel blooms, billets, and slabs include square sections 100×100 mm (4×4 in.) and larger, and rectangular sections at least $10,300 \text{ mm}^2$ (16 in.^2) in cross-sectional area.

Stainless Types. Blooms, billets, and slabs made of 4xx stainless steels that are highly hardenable (types 414, 420, 420F, 422, 431, 440A, 440B, and 440C) are annealed before shipment to prevent cracking. Other hardenable types, such as 403, 410, 416, and 416Se, also may be furnished in the annealed condition, depending on composition and size.

Processing. In general practice, blooms, billets, and slabs are cut to length by hot shearing. Hot sawing and flame cutting are also used. When the end distortion or burrs normally encountered in regular mill cutting are not acceptable, ends can be prepared for subsequent operations by any method that does not leave distortion or burrs. Usually, this is grinding. Blooms, billets, tube rounds, and slabs are surface conditioned by grinding or turning prior to being processed by hot rolling, hot forging, hot extruding, or hot piercing. Material can be tested by ultrasonic and macroetching techniques in the as-worked condition; however, a more critical evaluation is possible after the material has been conditioned. At the time an order is placed, producer and customer should come to an agreement regarding the manner in which testing or inspection is to be conducted and results interpreted.

Pipe, Tubes, and Tubing

Pipe, tubes, and tubing are hollow products made either by piercing rounds or by rolling and welding strip. They are used for conveying gases, liquids, and solids, and for various mechanical and structural purposes. (Cylindrical forms intended for use as containers for storage and shipping purposes and products cast to tubular shape are not included in this category.) The number of terms used in describing sizes and other characteristics of stainless steel tubular products has grown with the industry, and in some cases terms may be difficult to define or to distinguish from one another. For example, the terms pipe, tubes, and tubing are distinguished from one another only by general use, not by clear-cut rules. Pipe is distinguished from tubes chiefly by the fact that it is commonly produced in relatively few standard sizes. Tubing

is generally made to more exacting specifications than either pipe or tubes, regarding dimensions, finish, chemical composition, and mechanical properties.

Stainless steel tubular products are classified according to intended service, as described in the following paragraphs and tabular matter.

Stainless Steel Tubing for General Corrosion-Resisting Service. Straight chromium (ferritic or martensitic) types are produced in the annealed or heat-treated condition, and chromium-nickel (austenitic) types are produced in the annealed or cold-worked condition. Austenitic types are inherently tougher and more ductile than ferritic types for similar material conditions or tempers.

ASTM specifications A 268 and A 269 apply to stainless steel tubing for general service: A 268 applies to ferritic grades, and A 269, to austenitic grades. Most ferritic grades are also covered by ASME SA268, which sets forth the same material requirements as does ASTM A 268.

Stainless steel pressure pipe is made from straight chromium and chromium-nickel types and is governed by the specifications:

Specifications		Description
ASTM	ASME	
A 312	SA312	Seamless and welded pipe
A 358	SA358	Electric fusion welded pipe for high-temperature service
A 376	SA376	Seamless pipe for high-temperature central-station service
A 409	...	Large-diameter welded pipe for corrosion or high-temperature service
A 790	SA790	Seamless and welded ferritic/austenitic stainless steel pipe

Stainless steel pressure tubes include boiler, superheater, condenser, and heat-exchanger tubes, which commonly are manufactured from chromium-nickel types; requirements are set forth in the specifications:

Specifications		Description
ASTM	ASME	
A 213	SA213	Ferritic and austenitic alloy seamless tubes for boilers, superheaters, and heat exchangers

A 249	SA249	Austenitic alloy welded tubes for boilers, superheaters, heat exchangers, and condensers
A 271	SA271	Austenitic alloy seamless still tubes for refinery service
A 498	...	Ferritic and austenitic alloy seamless and welded tubes with integral fins
A 688	SA688	Welded austenitic stainless steel feedwater heater tubes
A 789	SA789	Seamless and welded ferritic/austenitic stainless steel tubing

Stainless steel sanitary tubing is used extensively in the dairy and food industries, where cleanliness and exceptional corrosion resistance are important surface characteristics. In many instances, even the slight amounts of corrosion that result in tarnishing or in release of a few ppm of metallic ions into the process stream are objectionable. Sanitary tubing may be polished on the outside or the inside, or both, to provide smooth, easily cleanable surfaces. Special finishes and close dimensional tolerances for special fittings are sometimes required. ASTM A 270 is in common use for this tubing.

Stainless steel mechanical tubing is produced in round, square, rectangular, and special-shape cross sections. It is used for many different applications, most of which do not require the tubing to be pressurized. Mechanical tubing is used for bushings; small cylinders; bearing parts; fittings; various types of hollow, cylindrical or ringlike formed parts; and structural members such as furniture frames, machinery frames, and architectural members. ASTM A 511 and A 554 apply to seamless and welded mechanical tubing, respectively.

Stainless steel aircraft tubing, produced from various chromium-nickel types, has many structural and hydraulic applications in aircraft construction because of its high resistance to both heat and corrosion. Work-hardened tubing can be used in high-strength applications, but it is not recommended for parts that may be exposed to certain corrosive substances or to certain combinations of corrosive static or fluctuating stress. Low-carbon types or compositions stabilized by titanium or by niobium with or without tantalum are commonly used when welding is to be done without subsequent heat treatment.

Aircraft tubing is made to close tolerances and with special surface finishes, special mechanical properties, and stringent requirements for testing and inspection. It is used for structural components of aircraft fuselages, engine mounts, engine oil lines, landing gear components, and engine parts and is finding increasing application in parts for hydraulic, fuel-injection, exhaust, and heating systems.

Aircraft structural tubing is both seamless and welded stainless steel tubing in sizes larger than those referred to as aircraft tubing. It is commonly used in exhaust systems (including stacks), cross headers, collector rings, engine parts, heaters, and pressurizers. Sometimes, stainless steel aircraft structural tubing is produced especially for parts that are to be machined. Stabilized types are used for welded and brazed structures.

Seamless and welded stainless steel aircraft structural tubing is made in sizes ranging from 1.6 to 125 mm ($\frac{1}{16}$ to 15 in.) in outside diameter and from 0.25 to 6.35 mm (0.010 to 0.250 in.) in wall thickness. It is ordinarily produced to the federal and Aerospace Material Specification (AMS) specifications listed below. However, because the U.S. government has embarked on a program of replacing military (MIL) specifications with AMS and ASTM specifications, the MIL specifications listed may no longer apply.

Specification	UNS number, composition, and condition
Seamless tubing	
AMS 5560	S30400; 19Cr-9Ni; annealed
AMS 5561	S21900; 21Cr-6Ni-9Mn; annealed
AMS 5570	S32100; 18Cr-11Ni (Ti stabilized); annealed
AMS 5571	S34700; 18Cr-11Ni (Nb + Ta stabilized); annealed
AMS 5572	S31008; 25Cr-20Ni; annealed
AMS 5573	S31600; 17Cr-12.5Ni-2.5Mo; annealed
AMS 5574	S30908; 23Cr-13.5Ni; annealed
AMS 5578	S45500; 12.5Cr-8.5Ni-0.03 (Nb + Ta)-1.1Ti-2.0Cu; annealed
Welded tubing	
MIL-T-6737	18-8 (stabilized); annealed
AMS 5565	S30400; 19Cr-9Ni; annealed
AMS 5575	S34700; 18Cr-11Ni (Nb + Ta stabilized); annealed
AMS 5576	S32100; 18Cr-10Ni (Ti stabilized); annealed
AMS 5577	S31008; 25Cr-20Ni; annealed
Seamless and welded tubing	
MIL-T-5695	18-8; hardened (cold worked)
MIL-T-8506	S30400; 18-8; annealed
MIL-T-8686	18-8 (stabilized); annealed

Aircraft Hydraulic-Line Tubing. Stainless steel tubing is used widely in aircraft and aerospace vehicles for fuel-injection lines and hydraulic systems. Most of the tubing used for such applications is relatively small; types 304, 304L, 321, 347, and 21-6-9 are most often specified. Aircraft hydraulic-line tubing must have high strength, high ductility, high fatigue resistance, high corrosion resistance, and good cold-working qualities. The ability to be flared for use with standard flare fittings, the ability to be bent without excessive distortion or fracture, and cleanliness of the inside surface are important requirements.

Stainless steel aircraft hydraulic-line tubing is produced in either the annealed or the cold-worked ($\frac{1}{8}$ hard) condition.

The $\frac{1}{8}$ hard temper is used wherever possible to save weight. Specifications for stainless steel aircraft hydraulic-line tubing, either seamless or welded, are:

Specification	UNS number, or type, and condition
MIL-T-6845	S30400; $\frac{1}{8}$ hard
MIL-T-8504	S30400; annealed
MIL-T-8808	321 or 347; annealed
AMS 5556	S34700; annealed
AMS 5557	S32100; annealed
AMS 5560	S30400; annealed
AMS 5566	S30400; $\frac{1}{8}$ hard

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Tensile Properties

Mechanical properties of most stainless steels, especially ductility and toughness, are higher than the same properties of carbon steels. Strength and hardness can be raised by cold work for ferritic and austenitic types, and by heat treatment for precipitation-hardening and martensitic types. Certain ferritic stainless steels can also be hardened slightly by heat treatment.

Austenitic Types. Basic room-temperature properties of standard austenitic stainless steels and of several nonstandard austenitic stainless steels are given in Tables 7 and 8. Additional specifications for austenitic stainless steels include:

Product form	ASTM specification
Wire	A 313, A 492, A 493, A 555, B 471, B 475
Bar and wire	B 649
Wire, bar, shapes	A 479
Billet and bar	A 314, B 472
Flanges, fittings, and/or valves, and so on	A 182, A 403, B 462, A 403
Bolting	A 193
Nuts	A 194

Table 7 Minimum room-temperature mechanical properties of austenitic stainless steels

Product form ^(a)	Condition	Tensile strength		0.2% yield strength		Elonga- tion, %	Reduction in area, %	Hardness, HRB	ASTM specification

Certain austenitic stainless steels--the so-called metastable types--can develop higher strengths and hardnesses than other stable types for a given amount of cold work. In metastable austenitic stainless steels, deformation triggers and transformation of austenite to martensite. The effect of this transformation on strength is shown in Fig. 4, which compares the stress-strain curve for stable type 304 with that for metastable type 301. The parabolic shape of the curve for type 304 indicates that strain hardening occurs throughout the duration of the application of stress, but that the amount of strain hardening for a given increment of stress decreases as stress increases.

Fig. 4 Typical stress-strain curves for types 301 and 304 stainless steel

On the other hand, type 301 continues to strain harden well into the plastic range. The extended strain hardening is the result of the deformation-induced transformation of austenite to martensite.

Ferritic types of stainless steel are defined as those that contain at least 10.5% Cr and that have microstructures of ferrite plus carbides. These steels are lower in toughness than the austenitic types. Basic room-temperature mechanical properties of ferritic stainless steels are given in Table 9. Strength is enhanced only moderately by cold working. Additional specifications for ferritic stainless steels include:

Duplex (Austenite/Ferrite) Types. Most wrought duplex stainless steels contain about 50% austenite-50% ferrite because of the balancing of elements that stabilize austenite (carbon, nitrogen, nickel, copper, and manganese) and ferrite (chromium, molybdenum, and silicon). Low carbon is maintained in most grades to minimize intergranular carbide precipitation. The austenite-ferrite balance provides wrought material with the optimum levels of mechanical properties and corrosion resistance. Because typically less austenite is present as-cast, welding consumables with enriched nickel are generally used to maintain austenite in the weld metal at levels generally similar to those in the base material.

Yield strengths approximately twice that of type 316 can be obtained with annealed duplex stainless steels. Basic room-temperature mechanical properties of duplex stainless steel are given in Table 10. Strength levels can be enhanced by cold working. Lower transverse ductility and impact strength can be expected because of the directional nature of the wrought micro-structure (typically elongated austenite islands in a ferrite matrix).

Martensitic types are iron-chromium steels with or without small additions of other alloying elements. They are ferritic in the annealed condition, but are martensitic after rapid cooling in air or a liquid medium from above the critical temperature. Steels in this group usually contain no more than 14% Cr--except types 440A, 440B, and 440C, which contain 16 to 18% Cr--and an amount of carbon sufficient to permit hardening. If other elements are present, the total concentration is usually no more than 2 to 3%. Martensitic stainless steels may be hardened and tempered in the same manner as alloy steels. They have excellent strength and are magnetic. Basic room-temperature properties of the martensitic types are given in Table 11 and Fig. 5. Additional specifications for martensitic stainless steels are:

Fig. 5 Typical hardnesses of selected martensitic stainless steels

Martensitic stainless steels harden when cooled off the mill after hot processing; therefore, they are often given a process anneal at 650 to 760 °C (1200 to 1400 °F) for about 4 h. Process annealing differs from full annealing, which is done by heating at 815 to 870 °C (1500 to 1600 °F), cooling in the furnace at a rate of 40 to 55 °C/h (75 to 100 °F/h) to about 540 °C (1000 °F), and then cooling in air to room temperature. Occasionally, martensitic types are purchased in the tempered condition; this condition is achieved by cooling directly off the mill to harden the steel and then reheating to a tempering temperature of 540 to 650 °C (1000 to 1200 °F), or by reheating the steel to a hardening temperature of 1010 to 1065 °C (1850 to 1950 °F), cooling it, and then tempering it. The influence of tempering temperature on the properties of hardened martensitic stainless steels is shown in Fig. 6. In heat treating martensitic stainless steels, temperatures up to about 480 °C (900 °F) are referred to as stress-relieved temperatures because little change in tensile properties occurs upon heating hardened material to these temperatures. Temperatures of 540 to 650 °C (1000 to 1200 °F) are referred to as tempering temperatures, and temperatures of 650 to 760 °C (1200 to 1400 °F) are called annealing temperatures.

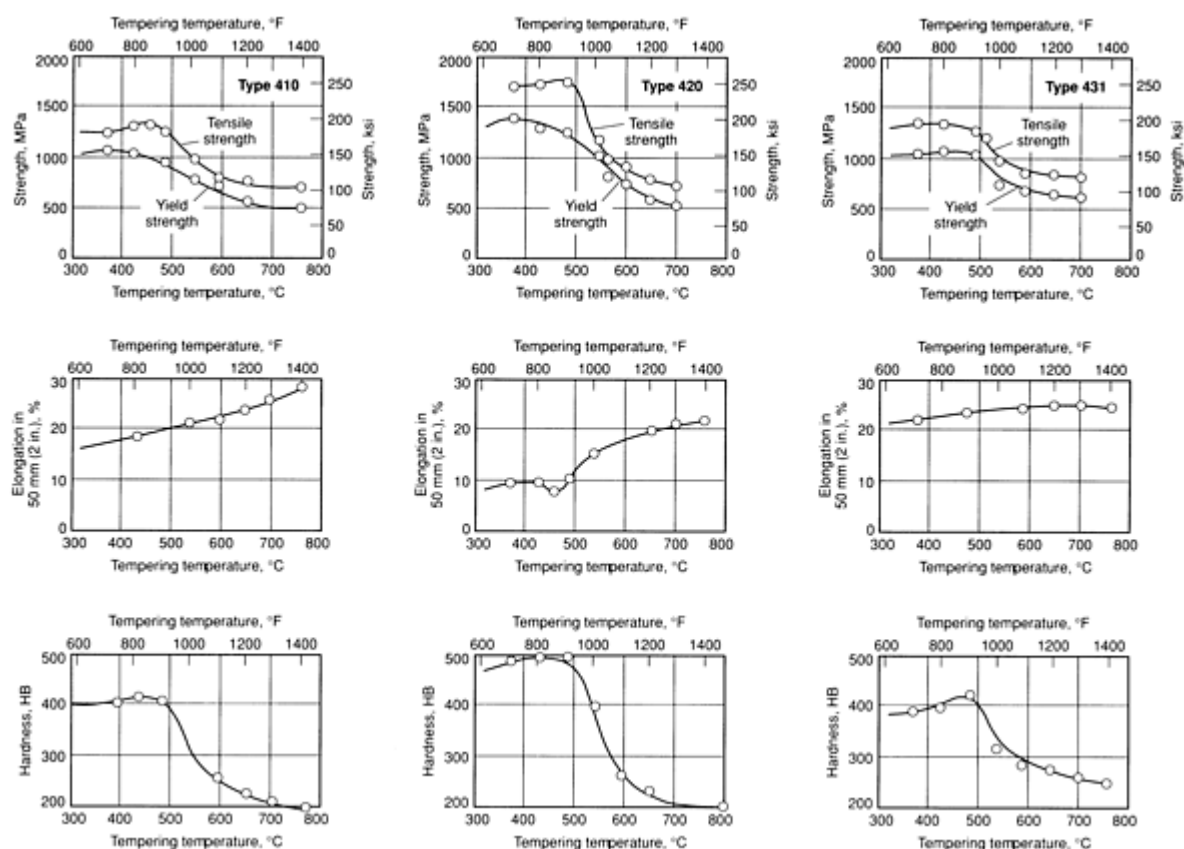

Fig. 6 Variation of tensile properties and hardness with tempering temperature for three martensitic stainless steels

Precipitation-hardening types are generally heat treated to final properties by the fabricator. Table 12 summarizes the minimum properties that can be expected in both material as received from the mill and material that has been properly heat treated.

(b) Higher value is longitudinal; lower value is transverse.

(c) Values vary with thickness or diameter.

(d) Longitudinal properties only.

(e) Higher values are for sizes up to and including 75 mm (3 in.); lower values are for sizes over 75 mm (3 in.) up to and including 200 mm (8 in.)

(f) Tensile strengths of 860 to 140 MPa (125 to 165 ksi) for sizes up to 13 mm ($\frac{1}{2}$ in.).

(g) Tensile strength only applicable up to sizes of 13 mm ($\frac{1}{2}$ in.).

(h) Varies with section size and test direction.

(i) Up to and including 150 mm (6 in.)

The precipitation-hardening stainless steels are of two general classes: single-treatment alloys and double-treatment alloys. Single-treatment alloys, such as Custom 450, 17-4 PH, and 15-5 PH, are solution annealed at about 1040 °C (1900 °F) to dissolve the hardening agent. Upon cooling to room temperature, the structure transforms to martensite that is supersaturated with respect to the hardening agent. A single tempering treatment at about 480 to 620 °C (900 to 1150 °F) is all that is required to precipitate a secondary phase to strengthen the alloy. As listed in Table 12, different tempering temperatures within this range produce different properties.

Double-treatment alloys such as 17-7 PH are solution treated at about 1040 °C (1900 °F) and then water quenched to retain the hardening agent in solution in an austenitic structure. The austenite is conditioned by heating to 760 °C (1400 °F) to precipitate carbides and thereby unbalance the austenite so that it transforms to martensite upon cooling to a temperature below 15 °C (60 °F); this treatment produces condition T. Alternatively, the austenite may be conditioned at a higher temperature, 925 °C (1700 °F), at which fewer carbides precipitate, and then may be transformed to martensite by cooling to room temperature, followed by refrigerating to -75 °C (-100 °F); this treatment produces condition R. Transformation can also be effected by severe cold work (about 60 to 70% reduction); such treatment produces condition C. Once the structure has been transformed to martensite by one of these three processes, tempering at 480 to 620 °C (900 to 1150 °F) induces precipitation of a secondary metallic phase, which strengthens the alloy. Properties developed by typical TH, RH, and CH treatments are given in Table 12 for 17-7 PH.

Notch Toughness and Transition Temperature

Notched-bar impact testing of stainless steels is likely to show a wide scatter in test results, regardless of type or test conditions. Because of this wide scatter, only general behavior of the different classes can be described.

Austenitic types have good notched-bar impact resistance. Charpy impact energies of 135 J (100 ft · lb) or greater are typical of all types at room temperature. Cryogenic temperatures have little or no effect on notch toughness; ordinarily, austenitic stainless steel maintain values exceeding 135 J even at very low temperatures. On the other hand, cold work lowers the resistance to impact at all temperatures.

Martensitic and ferritic stainless steels exhibit a decreasing resistance to impact with decreasing temperature, and the fracture appearance changes from a ductile mode at mildly elevated temperatures to a brittle mode at low temperatures. This fracture transition is characteristic of martensitic and ferritic materials. Both the upper-shelf energy and the lower-shelf energy are not greatly influenced by heat treatment in these stainless steels. However, the temperature range over which transition occurs is affected by heat treatment, minor variations in composition, and cold work. Heat treatments that result in high hardness move the transition range to higher temperatures, and those that result in low hardness move the transition range to lower temperatures. As indicated in Fig. 7, transition generally occurs in the range of -75 to 95 °C (-100 to 200 °F), which is the temperature range in which martensitic stainless steels are ordinarily used. Consequently, it may be necessary to investigate fracture behavior thoroughly before specifying a martensitic or ferritic stainless steel for a particular application.

Fig. 7 Typical transition behavior of type 410 martensitic stainless steel. All data from Charpy V-notch tests: A represents material tempered at 790 °C (1450 °F); final hardness, 95 HRB. B represents material tempered at 665 °C (1225 °F); final hardness, 24 HRC. C represents material tempered at 595 °C (1100 °F); final hardness, 30 HRC.

Fracture toughness data are not available for many of the standard types of stainless steel. Most testing has been concentrated on the high-strength precipitation-hardening stainless steels because these materials have been used in critical applications where fracture toughness testing has been found most useful for evaluating materials. Table 13 lists typical fracture toughness for several of the high-strength stainless steels for which this property has been determined.

Table 13 Longitudinal fracture toughness of precipitation-hardening (PH) stainless steels

Fatigue Strength

Three types of fatigue tests are used to develop data on the fatigue behavior of stainless steels:

- Rotating-beam test, the most commonly used, which most closely approximates the kind of loading to which shafts and axles are subjected
- Flexural fatigue test (used to evaluate the behavior of sheet), which most closely simulates the action of leaf springs, which are expected to flex without deforming or breaking
- Axial-load fatigue test, which subjects a fatigue specimen to unidirectional loading that can range from full reversal (tension-compression) to tension-tension loading and can have virtually any conceivable ratio of maximum stress to minimum stress

Fatigue data can be given in the form of stress-number of cycles (*S-N*) curves (Fig. 8) or constant-life diagrams (Fig. 9). Data from any of the three types of tests can be presented as *S-N* curves, but only data from flexural fatigue and axial fatigue tests can be presented in the form of a constant-life diagram. In analyzing fatigue data, and particularly in selecting materials on the basis of fatigue life, it is important to understand the influence of the stress ratio on fatigue life. In general, fatigue conditions involving tension-compression loading (stress ratio, *R*, between 0 and -1) lead to shorter fatigue lives than conditions involving tension-tension loading (stress ratio, *R*, between 0 and +1) at the same value of maximum stress.

Elevated-Temperature Properties

Many stainless steels--particularly the austenitic types 304, 309, 310, 316, 321, and 347 and certain precipitation-hardening types such as PH 15-7 Mo, 15-5 PH, 17-4 PH, 17-7 PH, AM-350, and AM-355--are used extensively for elevated-temperature applications such as chemical processing equipment, high-temperature heat exchangers, and superheater tubes for power boilers. For more details on the elevated-temperature properties of selected types, see the article "Elevated-Temperature Properties of Stainless Steels" in this Volume.

Extended service at elevated temperature can result in the embrittlement of stainless steels or in sensitization, which degrades the ability of the material to withstand corrosion, particularly in acid media. Most often, such degradation is caused by the precipitation of secondary phases such as carbides, α' phase, or σ phase. Precipitation depends on both time and temperature; longer times at temperature and higher temperatures within the precipitation temperature range promote more extensive precipitation. The problems arising from embrittlement and sensitization and the remedies that can help combat them are discussed in detail in the section "Fabrication Characteristics" in this article.

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Subzero-Temperature Properties

Austenitic stainless steels have been used extensively for subzero applications to -270°C (-450°F). These steels contain sufficient amounts of nickel and manganese to depress the temperature at which martensite starts to form from austenite upon cooling, M_s , into the subzero range. Thus they retain face-centered cubic (fcc) crystal structures upon cooling from hot working or annealing temperatures. Yield and tensile strengths of austenitic stainless steels increase substantially as testing temperature is decreased, and these steels retain good ductility and toughness at -270°C (-450°F). Most austenitic stainless steels may be readily fabricated by welding, but sometimes the welding heat causes sensitization that reduces corrosion resistance in the weld area. The strength of austenitic steels can be increased by cold rolling or cold drawing. Cold working at -195°C (-320°F) is more effective in increasing strength than cold working at room temperature. For metallurgically unstable stainless steels such as 301, 304, and 304L, plastic deformation at subzero temperatures causes partial transformation to martensite, which increases strength. For some cryogenic applications, it is desirable to use a stable stainless steel such as type 310.

Compositions of austenitic stainless steels of interest are presented in Table 3. Small amounts of nitrogen increase the strengths of these steels. Manganese additions are used in some steels to replace some of the nickel. Type 416 is a martensitic chromium stainless steel that is usually used in the quenched and tempered condition. It is included in this series because there are applications in rotating pumps and other machinery in which a magnetic material is needed to activate counters.

Types 301 and 310 have been used in the form of extrahard cold-rolled sheet to provide high strength in such applications as the liquid oxygen and liquid hydrogen tanks for Atlas and Centaur rockets. Joining was done by butt fusion welding, and reinforcing strips were spot welded to the tank along the weld joint. In another method for producing high-strength cylindrical tanks, welded preform tanks are fabricated from annealed type 301 stainless steel, submerged in liquid nitrogen while in a cylindrical die, and expanded (cryoformed) by pressurizing until the preform fits the die. The amount of strengthening depends on the amount of plastic deformation incurred in expanding the preform to the size of the die. Strengthening results from the dual effects of the cold working of the austenite and the partial transformation of the austenite to martensite.

Type 304 stainless steel is usually used in the annealed condition for tubing, pipes, and valves employed in the transfer of cryogenics; for Dewar flasks and storage tanks; and for structural components that do not require high strength.

Types 310 and 310S are considered metallurgically stable for all conditions of cryogenic exposure. Therefore, these steels are used for structural components in which maximum stability and a high degree of toughness are required at cryogenic temperatures.

Type 316 stainless steel is less stable than type 310, but tensile specimens of type 316 pulled to 0.2% offset (at the yield load) at -270°C (-450°F) showed no indication of martensite formation in the deformed regions (Ref 4). However, when tensile specimens of type 316 were pulled to fracture at -270°C (-450°F), the metallographic structures in the areas of the fractures transformed to approximately 50% martensite (Ref 5). Type 316 stainless steel is an important candidate material for structural components of superconducting and magnetic fusion machinery.

For higher-strength components of cryogenic structures, there are several stainless steels that contain significant amounts of manganese in place of some of the nickel, along with small additions of nitrogen and other elements that increase strength. Among these stainless steels are 21-6-9, Pyromet 538, Nitronic 40, and Nitronic 60.

Tensile Properties. Typical tensile properties of annealed 300 series austenitic stainless steels at room temperature and at subzero temperatures are presented in Table 14, and tensile properties of cold worked 300 series stainless steels are given in Table 15. Cold working substantially increases yield and tensile strengths and reduces ductility, but ductility and notch toughness of the cold-worked alloy are often sufficient for cryogenic applications. Tensile properties of other stainless steels are presented in Table 16. For the annealed alloys, the greatest effect of the nitrogen addition is to produce an increase in yield strength at cryogenic temperatures. The data for cold-worked AISI 202, a nitrogen-strengthened stainless steel, indicates how this alloy can be strengthened by cold working that results in reduced ductility. Because of its low ductility, alloy 416 is not recommended for use below -196 °C (-320 °F) except in nonstressed applications.

Results of tensile tests on stainless steel weldments at subzero temperatures, given in Table 17, may be significant in selecting stainless steels for cryogenic applications. Results of ultrasonic determinations of Young's modulus and Poisson's ratio for three stainless steels, shown in Fig. 10 and 11, serve to supplement the tensile data.

Fig. 11 Poisson's ratios for three austenitic stainless steels as determined ultrasonically. Source: Ref 23

Fracture Toughness. Fracture toughness data for stainless steels are limited because steels of this type that are suitable for use at cryogenic temperatures have very high toughness. The fracture toughness data that are available were obtained by the J-integral method and converted to $K_{Ic}(J)$ values. Such data for base metal and weldments are shown in Table 18. Fracture toughness of base metals are relatively high even at -269°C (-452°F); fracture toughness of fusion zones (FZ) of welds may be lower or higher than that of the base metal.

Table 18 Fracture toughness of austenitic stainless steels and weldments for compact tension specimens

Alloy and condition ^(a)	Form	Room-temperature yield strength	Orientation	Fracture toughness, (K_{Ic}), J, at

Fracture Crack Growth Rates. Available data for determining fatigue crack growth rates at room temperature and at subzero temperatures for austenitic stainless steels and weldments are presented in Table 19. The fatigue crack growth rates of the base metals are generally higher at room temperature than at subzero temperatures, or about equal at room temperature and at subzero temperatures, except for 21-6-9 stainless steel. For 21-6-9, fatigue crack growth rates are higher at -269 °C (-452 °F) than at room temperature. A log-log plot of the da/dN data for type 304 stainless steel is shown in Fig. 12. For this steel, fatigue crack growth rates are nearly the same, at the same values of ΔK , for room-temperature and cryogenic-temperature tests. Fatigue crack growth rates in the fusion zones of welds tend to be higher than in the base metal.

Fatigue Strength. The results of flexural and axial fatigue tests at 10^6 cycles on austenitic stainless steels at room temperature and at subzero temperatures are presented in Table 20. Fatigue strength increases as exposure temperature is decreased. Notched specimens have substantially lower fatigue strengths than corresponding unnotched specimens at all testing temperatures. Reducing the surface roughness of unnotched specimens improves fatigue strength.

Table 20 Results of fatigue life tests on austenitic stainless steels

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Influence of Product Form on Properties

The mechanical properties of cast or wrought stainless steels vary widely from group to group, vary less widely from type to type within groups, and may vary with product form for a given type. Because of the wide variation from group to group, one must first decide whether a martensitic, ferritic, austenitic, duplex, or precipitation-hardening stainless steel is most suitable for a given application. Once the appropriate group is selected, the method of fabrication or service conditions may then dictate which specific type is required.

Before typical properties of the various product forms are discussed, it is important that two key points about stainless steels be recognized. First, many stainless steels are manufactured and/or used in a heat-treated condition, that is, in some thermally treated condition other than process annealed or, typically, mill processed. When this is the case, a tabulation of typical properties may not give all the required information. Second, in many products strain hardening during fabrication is a very important consideration. All stainless steels strain harden to some degree depending on structure, alloy content, and amount of cold working. Consequently, for applications in which the service performance of the finished product depends on the enhancement of properties during fabrication, it is essential that the manufacturer determine this effect independently for each individual product. Here, techniques such as statistical-reliability testing are invaluable.

Cast Structures. Whether produced as ingot, slab, or billet in a mill or as shape castings in a foundry, cast structures can exhibit wide variations in properties. Because of the possible existence of large dendritic grains, intergranular phases, and alloy segregation, typical mechanical properties cannot be stated precisely and generally are inferior to those of any wrought structure. Detailed information on the composition and properties of cast stainless steels is given in the article "Cast Stainless Steels" in this Volume.

Hot Processing. The initial purpose of hot rolling or forging an ingot, slab, or billet is to refine the cast structure and improve mechanical properties. Hot reduced products and hot reduced and annealed products exhibit coarser grain structures and lower strengths than cold processed products. Grain size and shape depend chiefly on start and finish temperatures and on the method of hot reduction. For instance, cross-rolled hand mill plate will exhibit a more equiaxed grain structure than continuous hot rolled strip.

Hot reduction may be a final sizing operation, as in the case of hot-rolled bar, billet, plate, or bar flats, or it may be an intermediate processing step for products such as cold-finished bar, rod, and wire, and cold-rolled sheet and strip.

Typical properties of hot processed products and of hot processed and annealed products are different from those of either cast or cold reduced products. Hot processed products tend to have coarser grain sizes than cold reduced products.

Cold Reduced Products. When strained at ambient temperatures, all stainless steels tend to work harden, as shown in Fig. 13. Because recrystallization does not occur during cold working, the final properties of thermally treated products depend on:

- Amount of cold reduction (which helps determine the number of potential recrystallization sites)
- Type of mill thermal treatment (subcritical annealing, normalizing, or solution treatment)
- Time at any given temperature

Wrought products that have been cold reduced and annealed generally have finer grain sizes, which produce higher strengths than hot processed products. Cold reduced products sometimes exhibit greater differences between transverse and longitudinal properties than hot processed products.

Fig. 13 Typical effect of cold rolling on the tensile strength of selected stainless steels

Cold finishing is generally done to improve dimensional tolerances or surface finish or to raise mechanical strength. Cold-finished products--whether they have been previously hot worked and annealed or have been hot worked, cold worked, and annealed--have higher mechanical strength and slightly lower ductility than their process-annealed counterparts.

Wrought Stainless Steels

Physical Properties

There are relatively few applications for stainless steels in which physical properties are the determining factors in selection. However, there are many applications in which physical properties are important in product design. For instance, stainless steels are used for many elevated-temperature applications, often in conjunction with steels of lesser alloy content. Because austenitic stainless steels have higher coefficients of thermal expansion and lower thermal conductivities than carbon and alloy steels, these characteristics must be taken into account in the design of stainless steel-to-carbon steel or stainless steel-to-alloy steel products such as heat exchangers. In such products, differential thermal expansion imposes stresses on the unit that would not be present were the unit made entirely of carbon or alloy steel; also, if the heat-transfer surface is made of stainless steel, it must be larger than if it were made of carbon or alloy steel.

Typical physical properties of selected grades of annealed wrought stainless steels are given in Table 21. Physical properties may vary slightly with product form and size, but such variations are usually not of critical importance to the application.

Table 21 Typical physical properties of wrought stainless steels, annealed condition

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Corrosion Properties

Stainless steels are susceptible to several forms of localized corrosive attack. The avoidance of such localized corrosion is the focus of much of the effort involved in selecting stainless steel. Furthermore, the corrosion performance of stainless steels can be strongly affected by practices of design, fabrication, surface conditioning, and maintenance.

The selection of a grade of stainless steel for a particular application involves the consideration of many factors, but always begins with corrosion resistance. It is first necessary to characterize the probable service environment. It is not enough to consider only the design conditions. It is also necessary to consider the reasonably anticipated excursions or upsets in service conditions. The suitability of various grades can be estimated from laboratory tests or from documentation of field experience in comparable environments. Once the grades with adequate corrosion resistance have been identified, it is then appropriate to consider mechanical properties, ease of fabrication, the types and degree of risk present in the application, the availability of the necessary product forms, and cost.

Mechanism of Corrosion Resistance

The mechanism of corrosion protection for stainless steels differs from that for carbon steels, alloy steels, and most other metals. In these other cases, the formation of a barrier of true oxide separates the metal from the surrounding atmosphere. The degree of protection afforded by such an oxide is a function of the thickness of the oxide layer, its continuity, its coherence and adhesion to the metal, and the diffusivities of oxygen and metal in the oxide. In high-temperature oxidation, stainless steels use a generally similar model for corrosion protection. However, at low temperatures, stainless steels do not form a layer of true oxide. Instead, a passive film is formed. One mechanism that has been suggested is the formation of a film of hydrated oxide, but there is not total agreement on the nature of the oxide complex on the metal surface. However, the oxide film should be continuous, nonporous, insoluble, and self-healing if broken in the presence of oxygen.

Passivity exists under certain conditions for particular environments. The range of conditions over which passivity can be maintained depends on the precise environment and on the family and composition of the stainless steel. When conditions are favorable for maintaining passivity, stainless steels exhibit extremely low corrosion rates. If passivity is destroyed under conditions that do not permit the restoration of the passive film, stainless steel will corrode much like a carbon or low-alloy steel.

The presence of oxygen is essential to the corrosion resistance of a stainless steel. The corrosion resistance of stainless steel is at its maximum when the steel is boldly exposed and the surface is maintained free of deposits by a flowing bulk environment. Covering a portion of the surface, for example, by biofouling, painting, or installing a gasket, produces an oxygen-depleted region under the covered region. The oxygen-depleted region is anodic relative to the well-aerated boldly exposed surface, and a higher level of alloy content in the stainless steel is required to prevent corrosion.

With appropriate grade selection, stainless steel will perform for very long times with minimal corrosion, but an inadequate grade can corrode and perforate more rapidly than a plain carbon steel will fail by uniform corrosion. The selection of the appropriate grade of stainless steel, then, is a balancing of the desire to minimize cost and the risk of corrosion damage by excursions of environmental conditions during operation or downtime.

Confusion exists regarding the meaning of the term passivation. It is not necessary to chemically treat a stainless steel to obtain the passive film; the film forms spontaneously in the presence of oxygen. Most frequently, the function of passivation is to remove free iron, oxides, and other surface contamination. For example, in the steel mill, the stainless steel may be pickled in an acid solution, often a mixture of nitric and hydrofluoric acids ($\text{HNO}_3\text{-HF}$), to remove oxides formed in heat treatment. Once the surface is cleaned and the bulk composition of the stainless steel is exposed to air, the passive film forms immediately.

Effects of Composition

Chromium is the one element essential in forming the passive film. Other elements can influence the effectiveness of chromium in forming or maintaining the film, but no other element can, by itself, create the properties of stainless steel.

Chromium. The film is first observed at about 10.5% Cr, but it is rather weak at this composition and affords only mild atmospheric protection. Increasing the chromium content to 17 to 20%, typical of the austenitic stainless steels, or to 26 to 29%, as possible in the newer ferritic stainless steels, greatly increases the stability of the passive film. However, higher chromium may adversely affect mechanical properties, fabricability, weldability, or suitability for applications involving certain thermal exposures. Therefore, it is often more efficient to improve corrosion resistance by altering other elements, with or without some increase in chromium.

Nickel, in sufficient quantities, will stabilize the austenitic structure; this greatly enhances mechanical properties and fabrication characteristics. Nickel is effective in promoting repassivation, especially in reducing environments. Also, it is particularly useful in resisting corrosion in mineral acids. Increasing nickel content to about 8 to 10% decreases resistance to stress-corrosion cracking (SCC), but further increases begin to restore SCC resistance. Resistance to SCC in most service environments is achieved at about 30% Ni. In the newer ferritic grades, in which the nickel addition is less than that required to destabilize the ferritic phase, there are still substantial effects. In this range, nickel increases yield strength, toughness, and resistance to reducing acids, but makes the ferritic grades susceptible to SCC in concentrated magnesium chloride (MgCl_2) solutions.

Most chloride cracking testing has been carried out in accelerated test media such as boiling MgCl_2 solution (boiling point: 154°C , or 309°F) (Ref 32, 33, 34). All austenitic stainless steels are susceptible to chloride cracking (Fig. 14). It is noteworthy, however, that the higher-nickel types 310 and 314 were appreciably more resistant than the others. Although this solution causes rapid cracking, it does not necessarily simulate the cracking observed in field applications.

Fig. 14 Relative SCC behavior of austenitic stainless steels in boiling magnesium chloride. Source: Ref 35

Manganese in moderate quantities and in association with nickel additions will perform many of the functions attributed to nickel. However, total replacement of nickel by manganese is not practical. Very high-manganese steels have some unusual and useful mechanical properties, such as resistance to galling. Manganese interacts with sulfur in stainless steels to form manganese sulfides. The morphology and composition of these sulfides can have substantial effects on corrosion resistance, especially pitting resistance.

Molybdenum in combination with chromium is very effective in terms of stabilizing the passive film in the presence of chlorides. Molybdenum is especially effective in increasing resistance to the initiation of pitting and crevice corrosion.

Carbon is useful to the extent that it permits hardenability by heat treatment, which is the basis of the martensitic grades, and provides strength in the high-temperature applications of stainless steels. In all other applications, carbon is detrimental to corrosion resistance through its reaction with chromium. In the ferritic grades, carbon is also extremely detrimental to toughness.

Nitrogen is beneficial to austenitic stainless steels in that it enhances pitting resistance, retards the formation of the chromium-molybdenum σ phase, and strengthens the steel. Nitrogen is essential in the newer duplex grades for increasing the austenite content, diminishing chromium and molybdenum segregation, and raising the corrosion resistance of the austenitic phase. Nitrogen is highly detrimental to the mechanical properties of the ferritic grades and must be treated as comparable to carbon when a stabilizing element is added to the steel.

Forms of Corrosion of Stainless Steels

The various forms of corrosive attack will be briefly discussed in this section. Detailed information on each of these forms of corrosion is available in the Section "Forms of Corrosion" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

General (uniform) corrosion of a stainless steel suggests an environment capable of stripping the passive film from the surface and preventing repassivation. Such an occurrence could indicate an error in grade selection. An example is the exposure of a lower-chromium ferritic stainless steel to moderate concentration of hot sulfuric acid (H_2SO_4).

Galvanic corrosion results when two dissimilar metals are in electrical contact in a corrosive medium. As a highly corrosion-resistant metal, stainless steel can act as a cathode when in contact with a less noble metal, such as steel. The corrosion of steel parts, for example, steel bolts in a stainless steel construction, can be a significant problem. However, the effect can be used in a beneficial way for protecting critical stainless steel components within a larger steel construction. In the case of stainless steel connected to a more noble metal, the active-passive condition of the stainless steel must be considered. If the stainless steel is passive in the environment, galvanic interaction with a more noble metal is unlikely to produce significant corrosion. If the stainless steel is active or only marginally passive, galvanic interaction with a more noble metal will probably produce sustained rapid corrosion of the stainless steel without repassivation. The most important aspect of galvanic interaction for stainless steels is the need to select fasteners and weldments of adequate corrosion resistance relative to the bulk material, which is likely to have a much larger exposed area.

Pitting is a localized attack that can produce the penetration of a stainless steel with almost negligible weight loss to the total structure. Pitting is associated with a local discontinuity of the passive film. It can be a mechanical imperfection, such as an inclusion or surface damage, or it can be a local chemical breakdown of the film. Chloride is the most common agent for the initiation of pitting. Once a pit is formed, it in effect becomes a crevice; the local chemical environment is substantially more aggressive than the bulk environment. Therefore, very high flow rates over a stainless steel surface tend to reduce pitting corrosion; a high flow rate prevents the concentration of corrosive species in the pit. The stability of the passive film with respect to resistance to pitting initiation is controlled primarily by chromium and molybdenum. Minor alloying elements can also have an important effect by influencing the amount and type of inclusions (for example, sulfides) in the steel that can act as pitting sites.

Pitting initiation can also be influenced by surface condition, including the presence of deposits, and by temperature. For a particular environment, a grade of stainless steel may be characterized by a single temperature, or a very narrow range of temperatures, above which pitting will initiate and below which pitting will not initiate. It is therefore possible to select a grade that will not be subject to pitting attack if the chemical environment and temperature do not exceed the critical levels. If the range of operating conditions can be accurately characterized, a meaningful laboratory evaluation is possible. The formation of deposits in service can reduce the pitting temperature.

Although chloride is known to be the primary agent of pitting attack, it is not possible to establish a single critical chloride limit for each grade. The corrosivity of a particular concentration of chloride solution can be profoundly affected by the presence or absence of various other chemical species that may accelerate or inhibit corrosion. Chloride concentration may increase where evaporation or deposits occur. Because of the nature of pitting attack--rapid penetration with little total weight loss--it is rare for any significant amount of pitting to be acceptable in practical application.

Crevice corrosion can be considered a severe form of pitting. Any crevice, whether the result of a metal-to-metal joint, a gasket, fouling, or deposits, tends to restrict oxygen access, resulting in attack. In practice, it is extremely difficult to prevent all crevices, but every effort should be made to do so. Higher-chromium, and especially higher-molybdenum, grades are more resistant to crevice attack. Just as there is a critical pitting temperature for a particular environment, there is a critical crevice temperature. This temperature is specific to the geometry and nature of the crevice and to the precise corrosion environment for each grade. The critical crevice temperature can be useful in selecting an adequately resistant grade for a particular application.

Intergranular corrosion is a preferential attack at the grain boundaries of a stainless steel. It is generally the result of sensitization. This condition occurs when a thermal cycle leads to grain-boundary precipitation of a carbide, nitride, or intermetallic phase without providing sufficient time for chromium diffusion to fill the locally depleted region. A grain-boundary precipitate is not the point of attack; instead, the low-chromium region adjacent to the precipitate is susceptible.

Sensitization is not necessarily detrimental unless the grade is to be used in an environment capable of attacking the region. For example, elevated-temperature applications for stainless steel can operate with sensitized steel, but concern for intergranular attack must be given to possible corrosion during downtime when condensation might provide a corrosive medium. Because chromium provides corrosion resistance, sensitization also increases the susceptibility of chromium-depleted regions to other forms of corrosion, such as pitting, crevice corrosion, and stress-corrosion cracking (SCC). The thermal exposures required to sensitize a steel can be relatively brief, as in high-temperature service.

Stress-corrosion cracking is a corrosion mechanism in which the combination of a susceptible alloy, sustained tensile stress, and a particular environment leads to cracking of the metal. Stainless steels are particularly susceptible to SCC in chloride environments; temperature and the presence of oxygen tend to aggravate chloride SCC of stainless steels. Most ferritic and duplex stainless steels are either immune or highly resistant to SCC. All austenitic grades, especially AISI types 304 and 316, are susceptible to some degree. The highly alloyed austenitic grades are resistant to sodium chloride (NaCl) solutions, but crack readily in $MgCl_2$ solutions. Although some localized pitting or crevice corrosion probably precedes SCC, the amount of pitting or crevice attack may be so small that it is undetectable. Stress corrosion is difficult to detect while in progress, even when pervasive, and can lead to rapid catastrophic failures of pressurized equipment.

It is difficult to alleviate the environmental conditions that lead to SCC. The level of chlorides required to produce stress-corrosion cracking is very low. In operation, there can be evaporative concentration or a concentration in the surface film on a heat-rejecting surface. Temperature is often a process parameter, as in the case of a heat exchanger. Tensile stress is one parameter that might be controlled. However, the residual stresses associated with fabrication, welding, or thermal cycling, rather than design stresses, are often responsible for SCC, and even stress-relieving heat treatments do not completely eliminate these residual stresses.

Erosion-Corrosion. Corrosion of a metal or alloy can be accelerated when there is an abrasive removal of the protective oxide layer. This form of attack is especially significant when the thickness of the oxide layer is an important factor in determining corrosion resistance. In the case of a stainless steel, erosion of the passive film can lead to some acceleration of attack.

Oxidation. Because of their high chromium contents, stainless steels tend to be very resistant to oxidation. Important factors to be considered in the selection of stainless steel grades for high-temperature service are the stability of the composition and microstructure upon thermal exposure and the adherence of the oxide scale upon thermal cycling. Because many of the stainless steels used for high temperatures are austenitic grades with relatively high nickel contents, it is also necessary to be alert to the possibility of sulfidation attack.

Corrosion in Specific Environments

The selection of a suitable stainless steel for a specific environment requires consideration of several criteria. The first is corrosion resistance. Alloys are available that provide resistance to mild atmospheres (for example, type 430) or to many

food-processing environments (for example, type 304 stainless). Chemicals and more severe corrodents require type 316 or a more highly alloyed material, such as 20Cb-3 (UNS N08020). Factors that affect the corrosivity of an environment include the concentration of chemical species, pH, aeration, flow rate (velocity), impurities (such as chlorides), and temperature, including effects from heat transfer.

The second criterion is mechanical properties, or strength. High-strength materials often sacrifice resistance to some form of corrosion, particularly SCC.

Third, fabrication must be considered, including such factors as the ability of the steel to be machined, welded, or formed. Resistance of the fabricated article to the environment must be considered, for example, the ability of the material to resist attack in crevices that cannot be avoided in the design.

Fourth, total cost must be estimated, including initial alloy price, installed cost, and the effective life expectancy of the finished product. Finally, consideration must be given to product availability.

Many applications for stainless steels, particularly those involving heat exchangers, can be analyzed in terms of a process side and a water side. The process side is usually a specific chemical combination that has its own requirements for a stainless steel grade. The water side is common in many applications. This section will discuss the corrosivity of various environments for stainless steels.

Atmospheric Corrosion. The atmospheric contaminants most often responsible for the rusting of structural stainless steels are chlorides and metallic iron dust. Chloride contamination may originate from the calcium chloride (CaCl_2) used to make concrete or from exposure in marine or industrial locations. Iron contamination may occur during fabrication or erection of the structure. Contamination should be minimized, if possible.

The corrosivity of different atmospheric exposures can vary greatly and can dictate application of different grades of stainless steel. Rural atmospheres, uncontaminated by industrial fumes or coastal salt, are extremely mild in terms of corrosivity for stainless steel, even in areas of high humidity. Industrial or marine environments can be considerably more severe.

Table 22 demonstrates that resistance to staining can depend on the specific exposure. For example, several 300-series stainless steels showed no rust during long-term exposures in New York City. On the other hand, staining was observed after much shorter exposures at Niagara Falls in a severe industrial-chemical environment near plants producing chlorine and HCl.

Table 22 Atmospheric corrosion of austenitic stainless steels at two industrial sites

Type ^(a)	New York City (industrial)		Niagara Falls (industrial-chemical)	
	Exposure time, years	Specimen surface evaluation	Exposure time, years	Specimen surface evaluation
302	5	Free from rust stains	$< \frac{2}{3}$	Rust stains
302	26	Free from rust stains
304	26	Free from rust stains	<1	Rust stains
304	6	Covered with rust spots; pitted
347	26	Free from rust stains

316	23	Free from rust stains	$< \frac{2}{3}$	Slight stains
316	6	Slight rust spots, slightly pitted
317	$< \frac{2}{3}$	Slight stains
317	6	Slight stains
310	<1	Rust stains
310	6	Rust spots; pitted

(a) Solution-annealed sheet, 1.6 mm ($\frac{1}{16}$ in.) thick

Although marine environments can be severe, stainless steels often provide good resistance. Table 23 compares several AISI 300-series stainless steels after a 15-year exposure to a marine atmosphere 250 m (800 ft) from the ocean at Kure Beach, NC. Materials containing molybdenum exhibited only extremely slight rust stain, and all grades were easily cleaned to reveal a bright surface. Type 304 stainless steel may provide satisfactory resistance in many marine applications, but more highly alloyed grades are often selected when the stainless is sheltered from washing by the weather and is not cleaned regularly.

Table 23 Corrosion of AISI 300-series stainless steels in a marine atmosphere

Based on 15-year exposures 250 m (800 ft) from the ocean at Kure Beach, NC

AISI type	Average corrosion rate		Average depth of pits		Appearance ^(a)
	mm/year	mils/year	mm	mils

(a) All stains easily removed to reveal bright surface.

Types 302 and 304 stainless steels have had many successful architectural applications. Type 430 stainless steel has been used in many locations, but there have been problems. For example, this stainless steel rusted in sheltered areas after only a few months' exposure in an industrial environment. It was replaced by type 302, which provided satisfactory service. In more aggressive environments, such as marine or severely contaminated atmospheres, type 316 stainless steel is especially useful.

Stress-corrosion cracking is generally not a concern when austenitic or ferritic stainless steels are used in atmospheric exposures. Several austenitic stainless steels were exposed to a marine atmosphere at Kure Beach, NC. Annealed and quarter-hard wrought AISI types 201, 301, 302, 304, and 316 stainless steels were not susceptible to SCC. In the as-welded condition, only type 301 stainless steel experienced failure. Following sensitization at 650 °C (1200 °F) for 1.5 h and furnace cooling, failures were obtained only for materials with carbon contents of 0.043% or more (Ref 37).

Stress-corrosion cracking must be considered when quench-hardened martensitic stainless steels or precipitation-hardening grades are used in marine environments or in industrial locations in which chlorides are present. Several hardenable stainless grades were exposed as U-bends 25 m (80 ft) from the ocean at Kure Beach, NC. Most samples were cut longitudinally, and two alloys received different heat treatments to produce different hardness or strength levels. The results of the study (Table 24) indicated that Custom 450 stainless and stainless alloy 355 resisted cracking. Stainless alloy 355 failed in this type of test when fully hardened; resistance was imparted by the 540 °C (1000 °F) temper. Precipitation-hardenable grades are expected to exhibit improved corrosion resistance when higher aging temperatures (lower strengths) are used.

Table 24 SCC of U-bend test specimens 25 m (80 ft) from the ocean at Kure Beach, NC

Alloy	Final heat treatment	Hardness, HRC	Specimen orientation	Time to failure of each specimen, days ^(a)
Custom 450	Aged at 480 °C (900 °F)	42	Transverse	NF, NF, NF, NF, NF
Type 410	Tempered at 260 °C (500 °F)	45	Longitudinal	379, 379, 471
	Tempered at 550 °C (1025 °F)	35	Longitudinal	4, 4
Alloy 355	Tempered at 540 °C (1000 °F)	38	Longitudinal	NF, NF, NF

15Cr-7Ni-Mo	Aged at 510 °C (950 °F)	49	Longitudinal	1, 1, 1
17Cr-4Ni	Aged at 480 °C (900 °F)	42	Longitudinal	93, 129, NF
	Aged at 620 °C (1150 °F)	32	Longitudinal	93, 129, NF
14Cr-6Ni	Aged at 480 °C (900 °F)	39	Longitudinal	93, 872, NF

Source: Ref 38

(a) NF, no failure in over 4400 days for Custom 450 and in 1290 days for the other materials.

Resistance to SCC is of particular interest in the selection of high-strength stainless steels for fastener applications. Cracking of high-strength fasteners is possible and often results from hydrogen generation due to corrosion or contact with a less noble material, such as aluminum. Resistance to SCC can be improved by optimizing the heat treatment, as noted above.

Fasteners for atmospheric exposure have been fabricated from a wide variety of alloys. Type 430 and unhardened type 410 stainless steels have been used when moderate corrosion resistance is required in a lower-strength material. Better-than-average corrosion resistance has been obtained by using type 305 and Custom Flo 302HQ stainless steels when lower strength is acceptable.

Corrosion in Water. Water may vary from extremely pure to chemically treated water to highly concentrated chloride solutions, such as brackish water or seawater, which can be further concentrated by recycling. This chloride content poses the danger of pitting or crevice attack of stainless steels. When the application involves moderately increased temperatures, even as low as 45 °C (110 °F), and particularly where there is heat transfer into the chloride-containing medium, there is the possibility of SCC. It is useful to consider water with two general levels of chloride content: fresh water, which can have chloride levels up to approximately 600 ppm, and seawater, which encompasses brackish and severely contaminated waters. The corrosivity of a particular level of chloride can be strongly affected by the other chemical constituents present, making the water either more or less corrosive.

Permanganate ion (MnO_4^-), which is associated with the dumping of chemicals, has been related to the pitting of type 304 stainless steel. The presence of sulfur compounds and oxygen or other oxidizing agents can affect the corrosion of copper and copper alloys, but does not have very significant effects on stainless steels at ambient or slightly elevated temperatures (up to approximately 260 °C, or 500 °F).

In fresh water, type 304 stainless steel has provided excellent service for such items as valve parts, weirs, fasteners, and pump shafts in water and wastewater treatment plants. Custom 450 stainless steel has been used as shafts for large butterfly valves in potable water. The higher strength of a precipitation-hardenable stainless steel permits reduced shaft diameter and increased flow. Type 201 stainless steel has seen service in revetment mats to reduce shoreline erosion in fresh water. Type 316 stainless steel has been used as wire for microstrainers in tertiary sewage treatment and is suggested for waters containing minor amounts of chloride.

Seawater is a very corrosive environment for many materials. Stainless steels are more likely to be attacked in low-velocity seawater or at crevices resulting from equipment design or at attachments of barnacles. Types 304 and 316 stainless steels suffer deep pitting if the seawater flow rate decreases to below about 1.5 m/s (5 ft/s) because of the crevices produced by fouling organisms. However, in one study, type 316 stainless steel provided satisfactory service as tubing in the heat recovery section of a desalination test plant with relatively high flow rates (Ref 39).

The choice of stainless steel for seawater service can depend on whether stagnant conditions can be minimized or eliminated. For example, boat shafting of 17Cr-4Ni stainless steel has been used for trawlers where stagnant exposure and the associated pitting would not be expected to be a problem. When seagoing vessels are expected to lie idle for extended

periods of time, more resistant boat shaft materials, such as 22Cr-13Ni-5Mn stainless steel, are considered. Boat shafts with intermediate corrosion resistance are provided by 18Cr-2Ni-12Mn and high-nitrogen type 304 (type 304HN) stainless steels.

The most severe exposure conditions are often used in seawater test programs. In one example of such data, flat-rolled specimens of 11 commercially available alloys with several mill finishes were exposed to seawater (Table 25). Triplicate samples were prepared with plastic multiple-crevice washers, each containing 20 plateaus or crevices. These washers were affixed to both sides of each panel by using a torque of either 2.8 or 8.5 N · m (25 or 75 lbf · in.). The panels were exposed for up to 90 days in filtered seawater flowing at a velocity of less than 0.1 m/s (0.33 ft/s).

Table 25 Crevice corrosion indexes of several alloys in tests in filtered seawater

Mill-finished panels exposed for 30, 60, and 90 days to seawater at 30 °C (85 °F) flowing at less than 0.1 m/s (0.33 ft/s); crevice washers tightened to 2.8 or 8.5 N · m (25 or 75 lbf · in.)

Alloy	UNS designation	Number of sides (S) attacked ^(a)	Maximum pit depth (D)		Crevice corrosion index (S × D)
			mm	mils

(a) Total number of sides was 18.

(b) Also showed tunneling attack perpendicular to the upper edge, or attack at edges.

(c) Perforated by attack from both sides.

Table 25 gives the number of sides that experienced crevice attack and the maximum attack depth at any crevice for that alloy. A crevice corrosion index (CCI) was calculated by multiplying the maximum attack depth by the number of sides attacked. This provided a ranking system that accounts for both initiation and growth of attack. Lower values of the CCI imply improved resistance.

Attack in the above test does not mean that materials with high CCIs cannot be used in seawater. For example, 22Cr-13Ni-5Mn stainless steel with a CCI of 20 has proved to be a highly resistant boat shaft alloy. Some of the more resistant materials in the above tests have been used for utility condenser tubing. These alloys include MONIT, AL-29-4C, 254SMO, Sea-Cure, and AL-6XN.

The possibility of galvanic corrosion must be considered if stainless steel is to be used in contact with other metals in seawater. Figure 15 provides corrosion potentials in flowing seawater for several materials. Preferably, only those materials that exhibit closely related electrode potentials should be coupled to avoid attack of the less noble material. Galvanic differences have been used to advantage in the cathodic protection of stainless steel in seawater. Crevice corrosion and pitting of austenitic types 302 and 316 stainless steels have been prevented by cathodic protection, but types 410 and 430 stainless steels develop hydrogen blisters at current densities below those required for complete protection.

Fig. 15 Corrosion potentials of various metals and alloys in flowing seawater at 10 to 25 °C (50 to 80 °F). Flow rate was 2.5 to 4 m/s (8 to 13 ft/s); alloys are listed in order of the potential versus saturated calomel electrode (SCE) that they exhibited. Those metals and alloys indicated by black bar may become active and exhibit a potential near -0.5 V versus SCE in low velocity or poorly aerated water and in shielded areas. Source: Ref 41

Other factors that should be noted for applications of stainless steels in seawater include the effects of high velocity, aeration, and temperature. Stainless steels generally show excellent resistance to high velocities, impingement attack, and cavitation in seawater. Also, stainless steels provide optimum service in aerated seawater because a lack of aeration at a specific site often leads to crevice attack. Very little oxygen is required to maintain the passive film on a clean stainless surface. Increasing the temperature from ambient to about 50 °C (120 °F) often reduces the attack of stainless steels, possibly because of differences in the amount of dissolved oxygen, changes in the surface film, or changes in the resistance of the boldly exposed sample area (Ref 42). Further temperature increases can result in increased corrosion, such as SCC.

Corrosion in Chemical Environments. The selection of stainless steels for service in chemical environments requires consideration of all forms of corrosion, as well as impurity levels and degree of aeration. When an alloy with sufficient general corrosion resistance has been selected, care must be taken to ensure that the material will not fail by pitting or SCC due to chloride contamination. Aeration may be an important factor in corrosion, particularly in cases of borderline passivity. If dissimilar-metal contact or stray currents occur, the possibility of galvanic attack or hydrogen embrittlement must be considered.

Alloy selection also depends on fabrication and operation details. If a material is to be used in the as-welded or stress-relieved condition, it must resist intergranular attack in service after these thermal treatments. In chloride environments, the possibility of crevice corrosion must be considered when crevices are present because of equipment design or the formation of adherent deposits. Higher flow rates may prevent the formation of deposits, but in extreme cases may also cause accelerated attack because of erosion or cavitation. Increased operating temperatures generally increase corrosion. In heat-transfer applications, higher metal wall temperatures result in higher rates than expected from the lower temperature of the bulk solution. These and other items may require consideration in the selection of stainless steels, yet suitable materials continue to be chosen for a wide variety of chemical plant applications (see the article "Corrosion in the Chemical Processing Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

Some generalizations can be made regarding the performance of various categories of stainless steels in certain types of chemical environments. These observations relate to the compositions of the grades. For example, the presence of nickel and copper in some austenitic grades greatly enhances the resistance to H₂SO₄ compared to the resistance of the ferritic grades. However, combinations of chemicals that are encountered in practice can be either more or less corrosive than might be expected from the corrosivity of the individual components. Testing in actual or simulated environments is always recommended as the best procedure for selecting a stainless steel grade. Additional information describing service experience is available from alloy suppliers.

Mineral Acids. The resistance of stainless steel to acids depends on the hydrogen ion (H⁺) concentration and the oxidizing capacity of the acid, along with such material variables as chromium content, nickel content, carbon content, and heat treatment (Ref 43). For example, annealed stainless steel resists strong HNO₃ in spite of the low pH of the acid because HNO₃ is highly oxidizing and forms a passive film because of the chromium content of the alloy. On the other hand, stainless steels are rapidly attacked by strong HCl because a passive film is not easily attained. Even in strong HNO₃, stainless steels can be rapidly attacked if they contain sufficient amounts of carbon and are sensitized. Oxidizing species, such as ferric salts, result in reduced general corrosion in some acids, but can cause accelerated pitting attack if chloride ions (Cl⁻) are present.

In nitric acid (HNO₃), as noted above, stainless steels have broad applicability, primarily because of their chromium content. Most AISI 300-series stainless steels exhibit good or excellent resistance in the annealed condition in concentrations from 0 to 65% up to the boiling point. Figure 16 shows the good resistance of type 304 stainless steel, particularly when compared with the lower-chromium type 410 stainless steel. More severe environments at elevated temperatures require alloys with higher chromium. In HNO₃ cooler-condensers, such stainless alloys as 7-Mo PLUS (UNS S32950) and 2RE10 (UNS S31008) are candidates for service.

Fig. 16 Corrosion rates of various stainless steels in boiling HNO₃. Source: Ref 44

In sulfuric acid, stainless steels can approach the borderline between activity and passivity. Conventional ferritic grades, such as type 430, have limited use in H₂SO₄, but the newer ferritic grades containing higher chromium and molybdenum (for example, 28% Cr and 4% Mo) with additions of at least 0.25% Ni have shown good resistance in boiling 10% H₂SO₄ (Ref 45), but corrode rapidly when acid concentration is increased.

The conventional austenitic grades exhibit good resistance in very dilute or highly concentrated H₂SO₄ at slightly elevated temperatures. Acid of intermediate concentration is more aggressive, and conventional grades have very limited use. The resistance of several stainless steels in up to about 50% H₂SO₄ is shown in Fig. 17. Aeration or the addition of oxidizing species can significantly reduce the attack of stainless steels in H₂SO₄. This occurs because the more oxidizing environment is better able to maintain the chromium-rich passive oxide film.

Fig. 17 Corrosion rates of various stainless steels in underaerated H₂SO₄ at 20 °C (70 °F). Source: Ref 44

Improved resistance to H₂SO₄ has been obtained by using austenitic grades containing high levels of nickel and copper, such as 20Cb-3 stainless steel. In addition to reducing general corrosion, the increased nickel provides resistance to SCC. Because of its resistance to these forms of corrosion, 20Cb-3 stainless steel has been used for valve springs in H₂SO₄ service.

In phosphoric acid (H₃PO₄), conventional straight-chromium stainless steels have very limited general corrosion resistance and exhibit lower rates only in very dilute or more highly concentrated solutions. Conventional austenitic stainless steels provide useful general corrosion resistance over the full range of concentrations up to about 65 °C (150 °F); use at temperatures up to the boiling point is possible for acid concentrations up to about 40%.

In commercial applications, however, wet-process H₃PO₄ environments include impurities derived from the phosphate rock, such as chlorides, fluorides, and H₂SO₄. These three impurities accelerate corrosion, particularly pitting or crevice corrosion in the presence of the halogens. Higher-alloyed materials than the conventional austenitic stainless steels are required to resist wet-process H₃PO₄. Candidate materials include alloy 904L, alloy 28, 20Cb-3, 20Mo-4, and 20Mo-6 stainless steels.

Hydrochloric acid service is generally not an application for stainless steels, except perhaps for very dilute solutions at room temperature. Stainless materials can be susceptible to accelerated general corrosion, SCC, and pitting in HCl environments.

Sulfurous acid (H₂SO₃) is a reducing agent; several stainless steels have provided satisfactory service in H₂SO₃ environments. Conventional austenitic stainless steels have been used in sulfite digesters, and type 316, types 317, 20Cb-3, and cast Alloy Casting Institute (ACI) alloys CF-8M and CN-7M stainless steels have seen service in wet sulfur dioxide (SO₂) and H₂SO₃ environments. Cast stainless steels are discussed in the article "Cast Stainless Steels" in this Volume. Service life is improved by eliminating crevices, including those formed from the settling of suspended solids, or by using molybdenum-containing grades. In some environments, SCC is also a possibility.

Organic acids and compounds are generally less aggressive than mineral acids because they do not ionize as completely, but they can be corrosive to stainless steels, especially when impurities are present. The presence of oxidizing agents in the absence of chlorides can reduce corrosion rates.

For pure acetic acid, corrosion resistance has been obtained by using types 316 and 316L stainless steels over all concentrations up to the boiling point. Type 304 stainless steel may be considered in all concentrations below about 90% at temperatures up to the boiling point. Corrosion rates for several stainless steels in acetic acid are listed in Table 26. Impurities present in the manufacture of acetic acid, such as acetaldehyde, formic acid, chlorides, and propionic acid, are expected to increase the attack of stainless steels. Chlorides may cause pitting or SCC.

Table 26 Corrosion of austenitic stainless steels in boiling glacial acetic acid

Data are from averaged results of 11-, 12-, and 21-day field tests.

AISI type	Corrosion rate	
	mm/year	mils/year
304	0.46	18
321	1.19	47
347	1.04	41
308	1.35	53
310	0.99	39
316	0.015	0.6

Formic acid is one of the more aggressive organic acids, and corrosion rates can be higher in the condensing vapor than in the liquid. Type 304 stainless steel has been used at moderate temperatures. However, type 316 stainless steel or higher alloys, such as 20Cb-3, are often preferred, and high-alloy ferritic stainless steels containing 26% Cr and 1% Mo or 29% Cr and 4% Mo also show some promise.

The corrosivity of propionic and acrylic acids at a given temperature is generally similar to that of acetic acid. Impurities are important and may strongly affect the corrosion rate. In citric and tartaric acids, type 304 stainless steel has been used for moderate temperatures, and type 316 has been suggested for all concentrations up to the boiling point.

Most dry organic halides do not attack stainless steels, but the presence of water allows halide acids to form and can cause pitting or SCC. Therefore, care should be exercised when using stainless steels in organic halides to ensure that water is excluded.

Type 304 stainless steel has generally been satisfactory in aldehydes, in cellulose acetate at lower temperatures, and in fatty acids up to about 150 °C (300 °F); at higher temperatures, these chemicals require types 316 or 317. Type 316 stainless steel is also used in amines, phthalic anhydride, tar, and urea service.

Stainless steels have been used in the plastics and synthetic fiber industries. Types 420 and 440C stainless steels have been used as plastic mold steels. More resistant materials, such as Custom 450, have been used for extruding polyvinyl chloride (PVC) pipe. Spinnerettes, pack parts, and metering pumps of Custom 450 and Custom 455 stainless steels have been used in the synthetic fiber industry to produce nylon, rayon, and polyesters.

Alkalies. All stainless steels resist general corrosion by all concentrations of sodium hydroxide (NaOH) up to about 65 °C (150 °F). Types 304 and 316 stainless steels exhibit low rates of general corrosion in boiling NaOH up to early 20% concentration. Stress-corrosion cracking of these grades can occur at about 100 °C (212 °F). Good resistance to general corrosion and SCC in 50% NaOH at 135 °C (275 °F) is provided by E-Brite and 7-Mo stainless steels (Ref 47). In ammonia (NH₃) and ammonium hydroxide (NH₄OH), stainless steels have shown good resistance at all concentrations up to the boiling point.

Salts. Stainless steels are highly resistant to most neutral or alkaline nonhalide salts. In some cases, types 316 is preferred for its resistance to pitting, but even the higher-molybdenum type 317 stainless steel is readily attacked by sodium sulfide (Na₂S) solutions.

Halogen salts are more corrosive to stainless steels because of the ability of the halide ions to penetrate the passive film and cause pitting. Pitting is promoted in aerated or mildly acidic oxidizing solutions. Chlorides are generally more aggressive than the other halides in their ability to cause pitting.

Gases. At lower temperatures, most austenitic stainless steels resist chlorine or fluorine gas if the gas is completely dry. The presence of even small amounts of moisture results in accelerated attack, especially pitting, and possibly SCC.

At elevated temperatures, stainless steels resist oxidation primarily because of their chromium content. Increased nickel minimizes spalling when temperature cycling occurs. Table 27 lists generally accepted maximum safe service temperatures for wrought stainless steels. Maximum temperatures for intermittent service are lower for the austenitic stainless steels, but are higher for most of the martensitic and ferritic stainless steels listed.

Table 27 Generally accepted maximum service temperatures in air for AISI stainless steels

AISI type	Maximum service temperature			
	Intermittent service		Continuous service	
	°C	°F	°C	°F
Austenitic grades

420	735	1355	620	1150
440	815	1500	760	1400

Contamination of the air with water and CO₂ often increases corrosion at elevated temperatures. Increased attack can also occur because of sulfidation as a result of SO₂, H₂S, or sulfur vapor.

Carburization of stainless steels can occur in carbon monoxide (CO), methane (CH₄), and other hydrocarbons. Carburization can also occur when stainless steels contaminated with oil or grease are annealed without sufficient oxygen to burn off the carbon. This can occur during vacuum or inert-gas annealing, as well as in open-air annealing of oily parts with shapes that restrict air access. Chromium, silicon, and nickel are useful in combating carburization.

Nitriding can occur in dissociated NH₃ at high temperatures. Resistance to nitriding depends on alloy composition as well as NH₃ concentration, temperature, and pressure. Stainless steels are readily attacked in pure NH₃ at about 540 °C (1000 °F).

Liquid Metals. The 18-8 stainless steels are highly resistant to liquid sodium or sodium-potassium alloys. Mass transfer is not expected up to 540 °C (1000 °F) and remains at moderately low levels up to 870 °C (1600 °F). The accelerated attack of stainless steels in liquid sodium occurs with oxygen contamination, with a noticeable effect occurring at about 0.02% oxygen by weight (Ref 43).

Exposure to molten lead under dynamic conditions often results in mass transfer in common stainless alloy systems. Particularly severe corrosion can occur in strongly oxidizing conditions. Stainless steels are generally attacked by molten aluminum, zinc, antimony, bismuth, cadmium, and tin.

Corrosion in Various Applications

Every industry features a variety of applications encompassing a range of corrosion environments. This section characterizes the experience of each industry according to the corrosion problems most frequently encountered and suggests appropriate grade selections.

Food and Beverage Industry. Stainless steels have been relied upon in these applications because of the lack of corrosion products that could contaminate the process environment and because of the superior cleanability of the stainless steels. The corrosion environment often involves moderately to highly concentrated chlorides on the process side, often mixed with significant concentrations of organic acids. The water side can range from steam heating to brine cooling. Purity and sanitation standards require excellent resistance to pitting and crevice corrosion.

Foods such as vegetables represent milder environments and can generally be handled by using type 304 stainless steel. Sauces and pickle liquors, however, are more aggressive and can pit even type 316 stainless steel. For improved pitting resistance, such alloys as 22Cr-13Ni-5Mn, 904L, 20Mo-4, 254SMO, AL-6XN, and MONIT stainless steels should be considered.

At elevated temperatures, materials must be selected for resistance to pitting and SCC in the presence of chlorides. Stress corrosion must be avoided in heat transfer applications, such as steam jacketing for cooking or processing vessels or in heat exchangers. Cracking may occur from the process or water side or may initiate outside the unit under chloride-containing insulation. Brewery applications of austenitic stainless steels have been generally successful except for a number of cases of the SCC of high-temperature water lines. The use of ferritic or duplex stainless steels is an appropriate remedy for the SCC. More information on this subject is available in the article "Corrosion in the Brewery Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Stainless steel equipment should be cleaned frequently to prolong its service life. The equipment should be flushed with fresh water, scrubbed with a nylon brush and detergent, and rinsed. On the other hand, consideration should be given to the effect of very aggressive cleaning procedures on the stainless steels, as in the chemical sterilization of commercial dishwashers. In some cases, it may be necessary to select a more highly alloyed stainless steel grade to deal with these brief exposure to highly aggressive environments.

Conventional AISI grades provide satisfactory service in many food and beverage applications. Type 304 stainless steel is widely used in the dairy industry, and type 316 finds application as piping and tubing in breweries. These grades, along with type 444 and Custom 450 stainless steels, have been used for chains to transfer food through processing equipment.

Machined parts for beverage-dispensing equipment have been fabricated from types 304, 304L, 316, 316L, and 303A1 MODIFIED, 302HQ-FM, and 303BV stainless steels. When the free-machining grades are used, it is important to passivate and rinse properly before service in order to optimize corrosion resistance.

Food-handling equipment should be designed without crevices in which food can become lodged. In more corrosive food products, extralow-carbon stainless steels should be used when possible. Improved results have been obtained when equipment is finished with a 2B (general-purpose cold-rolled) finish rather than No. 4 (general-purpose polished) finish. Alternatively, an electropolished surface may be considered.

Pharmaceutical Industry. The production and handling of drugs and other medical applications require exceedingly high standards for preserving the sterility and purity of process streams. Process environments can include complex organic compounds, strong acids, chloride solutions comparable to seawater, and elevated processing temperatures. Higher-alloy grades, such as type 316 or higher, may be necessary instead of type 304 in order to prevent even superficial corrosion. Electropolishing may be desirable in order to reduce or prevent adherent deposits and the possibility of underdeposit corrosion. Superior cleanability and ease of inspection make stainless steel the preferred material.

The 18-8 stainless grades have been used for a wide variety of applications from pill punches to operating tables. However, care is required in selecting stainless steels for pharmaceutical applications because small amounts of contamination can be objectionable. For example, stainless steel has been used to process vitamin C, but copper must be eliminated because copper in aqueous solutions accelerates the decomposition of vitamin C. Also, stainless steel is not used to handle vitamin B₆ hydrochloride, even though corrosion rates may be low, because trace amounts of iron are objectionable (see the Section "Specialty Steels and Heat-Resistant Alloys" in *Properties and Selection: Irons, Steels, and High-Performance Alloys*, Volume 1 of *ASM Handbook*).

The effects of temperature and chloride concentration must be considered. At ambient temperature, chloride pitting of 18Cr-8Ni stainless steel may occur, but SCC is unlikely. At about 65 °C (150 °F) or above, the SCC of austenitic grades must be considered. Duplex alloys, such as 7-Mo PLUS, alloy 2205, and Ferralium 255, possess improved resistance to SCC in elevated-temperature chloride environments. Ferritic grades with lower nickel content, such as 18Cr-2Mo stainless steel, provide another means of avoiding chloride SCC. Additional information on the use of stainless steels in the pharmaceutical industry is available in the article "Corrosion in the Pharmaceutical Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Stainless steels have also found application as orthopedic implants. Material is required that is capable of moderately high strength and resistance to wear and fretting corrosion and to pitting and crevice attack. Vacuum-melted type 316 stainless steel has been used for temporary internal fixing devices, such as bone plates, screws, pins, and suture wire. Higher purity improves electropolishing and increased chromium (17 to 19%) improves corrosion resistance.

In permanent implants, such as artificial joints, very high strength and resistance to wear, fatigue, and corrosion are essential. Cobalt- or titanium-base alloys are used for these applications. More information on this subject is available in the article "Corrosion of Metallic Implants and Prosthetic Devices" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Oil and Gas Industry. Stainless steels were not frequently used in oil and gas production until the tapping of sour reservoirs (those containing hydrogen sulfide, H₂S) and the use of enhanced recovery systems in the mid-1970s. Sour environments can result in sulfide stress cracking (SSC) of susceptible materials. This phenomenon generally occurs at ambient or slightly elevated temperatures; it is difficult to establish an accurate temperature maximum for all alloys. Factors affecting SSC resistance include material variables, pH, H₂S concentration, total pressure, maximum tensile stress, temperature, and time. A description of some of these factors, along with information on materials that have demonstrated resistance to SSC, is available in Ref 49.

The resistance of stainless steels to SSC improves with reduced hardness. Conventional materials, such as types 410, 430, and 304 stainless steels exhibit acceptable resistance at hardnesses below 22 HRC. Specialized grades, such as 22Cr-13Ni-5Mn, Custom 450, 20Mo-4, and some duplex stainless steels, have demonstrated resistance at higher hardnesses. Duplex alloy 2205 has been used for its strength and corrosion resistance as gathering lines for CO₂ gas before gas cleaning. Custom 450 and 22Cr-13Ni-5Mn stainless steels have seen service as valve parts. Other grades used in these environments include 254SMO and alloy 28, particularly for chloride and sulfide resistance, respectively.

In addition to the lower-temperature SSC, resistance to cracking in high-temperature environments is required in many oil field applications. Most stainless steels, including austenitic and duplex grades, are known to be susceptible to elevated-temperature cracking, probably by a mechanism similar to chloride SCC. Failure appears to be accelerated by H₂S and other sulfur compounds. Increased susceptibility is noted in material of higher yield strength, for example, because of the high residual tensile stresses imparted by some cold-working operations.

The above discussion is pertinent to the production phase of a well. However, drilling takes place in an environment of drilling mud, which usually consists of water, clay, weighting materials, and an inhibitor (frequently an oxygen scavenger). Chlorides are also present when drilling through salt formations. Austenitic stainless steels containing nitrogen have found use in this environment as nonmagnetic drill collars, as weight for the drill bit, and as housings for measurement-while-drilling (MWD) instruments. Nonmagnetic materials are required for the operation of these instruments, which are used to locate the drill bit in directional-drilling operations. Stainless steels used as drill collars or measurement-while-drilling components include the standard 316LN type stainless steel (Table 2) and several nonstandard stainless steels. More information on corrosion during petroleum production is available in the article "Corrosion in Petroleum Production Operations" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

In refinery applications, the raw crude contains such impurities as sulfur, water, salts, organic acids, and organic nitrogen compounds. These and other corrosives and their products must be considered in providing stainless steels for the various refinery steps.

Raw crude is separated into materials from petroleum gas to various oils by fractional distillation. These materials are then treated to remove impurities, such as CO₂, NH₃, and H₂S, and to optimize product quality. Refinery applications of stainless steels often involve heat exchangers. Duplex and ferritic grades have been used in this application for their improved SCC resistance. Type 430 and type 444 stainless steel exchanger tubing has been used for resisting hydrogen, chlorides, and sulfur and nitrogen compounds in oil refinery streams. The article "Corrosion in Petroleum Refining and Petrochemical Operations" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*, contains detailed information on the corrosion of materials in these applications.

Power Industry. Stainless steels are used in the power industry for generator components, feedwater heaters, boiler applications, heat exchangers, condenser tubing, flue gas desulfurization (FGD) systems, and nuclear power applications.

Generator blades and vanes have been fabricated of modified 12% Cr stainless steel, such as ASTM types 615 (UNS S41800) and 616 (UNS S42200). In some equipment, Custom 450 has replaced AISI type 410 and ASTM type 616 stainless steels.

Heat Exchangers. Stainless steels have been widely used in tubing for surface condensers and feedwater heaters. Both of these are shell and tube heat exchangers that condense steam from the turbine on the shell side. In these heat exchangers, the severity of the corrosion increases with higher temperatures and pressures. Stainless steels resist failure by erosion and do not suffer SCC in NH₃ (from the decomposition of boiler feedwater additives), as do some nonferrous materials.

Stainless steels must be chosen to resist chloride pitting. The amount of chloride that can be tolerated is expected to be higher with a higher pH and cleaner stainless steel surfaces, that is, the absence of deposits. For example, type 304 stainless steel may resist pitting in chloride levels of 1000 ppm or higher in the absence of fouling, crevices, or stagnant conditions. The presence of one or more of these conditions can allow chlorides to concentrate at the metal surface and initiate pits. Several high-performance stainless steels have been used to resist chloride pitting in brackish water or seawater. High-performance austenitic grades have been useful in feedwater heaters, although duplex stainless steels may also be considered because of their high strength. Ferritic stainless steels have proved to be economically competitive in exchangers and condensers. High-performance austenitic and ferritic grades have been satisfactory for seawater-cooled units. These grades include MONIT, AL-29-4C, Usinor 290 Mo, Sea-Cure, AL-6X, AL-6XN, and 254SMO stainless steels.

Compatibility of materials and good installation practice are required. Tubes of such materials as those listed above have been installed in tubesheets fabricated of alloy 904L, 20Mo-4, and 254SMO stainless steels. Crevice corrosion can occur when some tube materials are rolled into type 316 stainless steel tubesheets (Ref 50). Appropriate levels of cathodic protection have been identified (Ref 51).

Flue Gas Desulfurization. A wide variety of alloys have been used in scrubbers, which are located between the boiler and smokestack of fossil fuel power plants to treat effluent gases and to remove SO₂ and other pollutants. Typically, fly ash is removed, and the gas travels through an inlet gas duct and then the quencher section. Next, SO₂ is removed in the absorber section, most often using either a lime or limestone system. A mist eliminator is employed to remove suspended droplets, and the gas proceeds to the treated-gas duct, reheater section, and the stack.

Two important items for consideration in selecting stainless steels for resistance to pitting in scrubber environments are pH and chloride level. Stainless steels are more resistant to higher pH and lower chloride levels, as shown in Fig. 18 for type 316L stainless steel. Environments that cause the pitting or crevice attack of type 316 stainless steel can be handled by using higher-alloy materials, for example, those with increased molybdenum and chromium.

Fig. 18 Pitting of type 316L stainless steel in flue gas desulfurization scrubber environments. Solid lines indicate zones of differing severity of corrosion; because the zones are not clearly defined, the lines cannot be precisely drawn. Source: Ref 52

Some of the materials being considered and specified for varying chloride levels are given in Ref 53. Other materials can also provide good resistance, as evidenced by the results given in Table 28 for samples exposed to several scrubber environments. The maximum depth of localized corrosion and pit density are given for the stainless steels tested. Exposure at the quencher spray header (above slurry) was more severe than expected, probably because of wet-dry concentration effects. Severe attack also occurred in the outlet duct. Samples in this area were exposed to high chlorides, high temperatures, and low pH during the 39 days on bypass operation. More information on corrosion in fossil fuel power generation is available in the article "Corrosion in Fossil Fuel Power Plants" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*; corrosion in FGD systems is also discussed in the article "Corrosion of Emission-Control Equipment" in Volume 13 of *ASM Handbook*.

Table 28 Pitting of stainless steel spool test specimens in an FGD system

The slurry contained 7000 ppm dissolved Cl⁻ test duration was 6 months, with 39 days on bypass.

Spool location ^(a)	pH	Maximum temperature		Maximum chloride concentration, ppm	Maximum pit depth, mm (mils), and pit density							
		°C	°F		Type 304	Type 316L	Type 317L	Type 317LM	JS700	JS777	904L	20Mo-6

- (a) Slurry contained 7000 ppm dissolved Cl^- . Deposits in the quencher, inlet duct, absorber, and outlet ducting contained 3000 to 4000 ppm Cl^- and 800 to 1900 ppm F^- .
- (b) Present as halide gases.
- (c) Not tested.
- (d) During operation.
- (e) During bypass. Bypass condition gas stream contained SO_2 , SO_3 , HCl , HF , and condensate.

Nuclear Power Applications. Type 304 stainless steel piping has been used in boiling-water nuclear reactor plants. The operating temperatures of these reactors are about 290 °C (550 °F), and a wide range of conditions can be present during startup, operation, and shutdown. Because these pipes are joined by welding, there is a possibility of sensitization. This can result in intergranular SCC in chloride-free high-temperature water that contains small amounts of oxygen, for example, 0.2 to 8 ppm. Nondestructive electrochemical tests have been used to evaluate weldments for this service (Ref 55).

Type 304 stainless steel with additions of boron (about 1%) has been used to construct spent-fuel storage units, dry storage casks, and transportation casks. The high boron level provides neutron-absorbing properties. More information on nuclear applications is available in the article "Corrosion in the Nuclear Power Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Pulp and Paper Industry. In the kraft process, paper is produced by digesting wood chips with a mixture of Na_2S and NaOH (white liquor). The product is transferred to the brown stock washers to remove the liquor (black liquor) from brown pulp. After screening, the pulp may go directly to the paper mill to produce unbleached paper or may be directed first to the bleach plant to produce white paper.

The digester vapors are condensed, and the condensate is pumped to the brown stock washers. The black liquor from these washers is concentrated and burned with sodium sulfate (Na_2SO_4) to recover sodium carbonate (Na_2CO_3) and Na_2S . After dissolution in water, this green liquor is treated with calcium hydroxide ($\text{Ca}(\text{OH})_2$) to produce NaOH to replenish the white liquor. Pulp bleaching involves treating with various chemicals, including chlorine, chlorine dioxide (ClO_2), sodium hypochlorite (NaClO), calcium hypochlorite ($\text{Ca}(\text{ClO})_2$), peroxide, caustic soda, quicklime, and oxygen.

The sulfite process uses a liquor in the digester that is different from that used in the kraft process. This liquor contains free SO_2 dissolved in water, along with SO_2 as a bisulfite. The compositions of the specific liquors differ, and the pH can range from 1 for an acid process to 10 for alkaline cooking. Sulfur dioxide for the cooking liquor is produced by burning elemental sulfur, cooling rapidly, absorbing the SO_2 in a weak alkaline solution, and fortifying the raw acid.

Various alloys are selected for the wide range of corrosion conditions encountered in pulp and paper mills. Paper mill headboxes are typically fabricated from type 316L stainless steel plate with superior surface finish and are sometimes electropolished to prevent scaling, which may affect pulp flow. The blades used to remove paper from the drums are fabricated from types 410 and 420 stainless steels and from cold reduced 22Cr-13Ni-5Mn stainless steel.

Evaporators and reheaters must deal with corrosive liquors and must minimize scaling to provide optimum heat transfer. Type 304 stainless steel ferrite-free welded tubing has been used in kraft black-liquor evaporators. Cleaning is often performed with HCl , which attacks ferrite. In the sulfite process, type 316 (>2.75% Mo) and type 317 stainless steels have been used in black-liquor evaporators. Digester-liquor heaters in the kraft and sulfite processes have used 7-Mo stainless for resistance to caustic or chloride SCC.

Bleach plants have used types 316 and 317 stainless steels and are upgrading to austenitic grades containing 4.5 and 6% Mo in problem locations. The tightening of environmental regulations has generally increased temperature, chloride level,

and acidity in the plant, and this requires grades of stainless steel that are more highly alloyed than those used in the past. Tall oil units have shifted from types 316 and 317 stainless steels to such candidate alloys as 904L and 20Mo-4 stainless steels and most recently to 254SMO and 20Mo-6 stainless steels.

Tests including higher-alloyed materials have been coordinated by the Metals Subcommittee of the Corrosion and Materials Engineering Committee of the Technical Association of the Pulp and Paper Industry (TAPPI). Racks of test samples, which included crevices of polytetrafluoroethylene (PTFE) spacers, were submerged in the vat below the washer in the C (chlorination), D (chlorine dioxide), and H (hypochlorite) stages of several paper mills. The sum of the maximum attack depth on all samples for each alloy--at crevices and remote from crevices--is shown in Fig. 19(a), 19(b), and 19(c). It should be noted that the vertical axes are different in Fig. 19(a), 19(b), and 19(c). Additional information on corrosion in this industry is available in the article "Corrosion in the Pulp and Paper Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Fig. 19(a) Resistance of austenitic stainless steels containing 2.1 to 4.4% Mo to localized corrosion in a paper mill bleach plant environment. Total depth of attack has been divided by 4 because there were four crevice sites per specimen. See also Fig. 19(b) and 19(c). Source: Ref 56

Fig. 19(b) Resistance of austenitic stainless steels containing 4.4 to 7.0% Mo to localized corrosion in a paper mill bleach plant environment. Total depth of attack has been divided by 4 because there were four crevice sites per specimen. See also Fig. 19(a) and 19(c). Source: Ref 56

Transportation Industry. A wide range of functional and decorative components for transportation vehicles are fabricated from stainless steels.

Automobile. Bright automobile parts, such as trim, fasteners, wheel covers, mirror mounts, and windshield wiper arms, have generally been fabricated from 17Cr or 18Cr-8Ni stainless steel or similar grades. Example alloys include types 430, 434, 304, and 305 stainless steels. Type 302HQ-FM remains a candidate for such applications as wheel nuts, and Custom 455 stainless has been used as wheel lock nuts. The use of type 301 stainless steel for wheel covers has diminished with the weight reduction programs of the automotive industry.

Stainless steels also serve many nondecorative functions in automotive design. Small-diameter shafts of type 416 and, occasionally, type 303 stainless steels have been used in connection with power equipment, such as windows, door locks, and antennas. Solenoid grades, such as type 430FR stainless steels, have also found application. Type 409 stainless steel has been used for mufflers and catalytic converters for many years, but it is now being-employed through the exhaust system. The article "Corrosion in the Automotive Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*, contains detailed information on corrosion in the automotive environment.

Railroad Cars and Large Vehicles. In railroad cars, external and structural stainless steels provide durability, low-cost maintenance, and superior safety through crashworthiness. The fire resistance of stainless steel is a significant safety advantage. Modified type 409 stainless steel is used as a structural component in buses. Types 430 and 304 are used for exposed functional parts on buses. Type 304 stainless steel has provided economical performance in truck trailers. For tank trucks, type 304 has been the most frequently used stainless steel, but type 316 and higher-alloyed grades have been used where appropriate to carry more corrosive chemicals safely over the highways.

Ships. Stainless steels are used for seagoing chemical tankers with types 304, 316, 317, and alloy 2205 being selected according to the corrosivity of the cargoes being carried. Conscientious adherence to cleaning procedures between cargo changeovers has allowed these grades to give many years of service with a great variety of corrosive cargoes.

Aerospace. In aerospace, quench-hardenable and precipitation-hardenable stainless steels have been used in varying applications. Heat treatments are chosen to optimize fracture toughness and resistance to SCC. Stainless steel grades 15-5PH and PH13-8Mo have been used in structural parts, and PH3-8Mo stainless steel has served as fasteners. Parts in cooler sections of the engine have been fabricated from type 410 stainless steel. Custom 455, 17-4PH, 17-7PH, and 15-5PH stainless steels have been used in the space shuttle program (see the articles "Corrosion in the Aircraft Industry" and "Corrosion in the Aerospace Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

Architectural Applications. Typically, types 430 or 304 have been used in architectural applications. In bold exposure, these grades are generally satisfactory; however, in marine and industrially contaminated atmospheres, type 316 is often suggested and has performed well (see the article "Corrosion in Structures" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

In all applications, but particularly in the cases listed above in which appearance is important, it is essential that any chemical cleaning solutions be thoroughly rinsed from the metal.

Corrosion Testing

The physical and financial risks involved in selecting stainless steels for particular applications can be reduced through consideration of corrosion tests. However, care must be taken when selecting a corrosion test. The test must relate to the type of corrosion possible in the application. The steel should be tested in the condition in which it will be applied. The test conditions should be representative of the operating conditions and all reasonably anticipated excursions of operating conditions.

Corrosion tests vary in their degree of simulation of operation in terms of the design of the specimen and the selection of medium and test conditions. Standard tests use specimens of defined nature and geometry exposed in precisely defined media and conditions. Standard tests can confirm that a particular lot of steel conforms to the level of performance of standard and proprietary grades. The relevance of test results to performance in particular applications increases as the specimen is made to resemble more closely the final fabricated structure, for example, bent, welded, stressed, or creviced. Relevance also increases as the test medium and conditions more closely approach the most severe operating conditions. However, many types of failures occur only after extended exposures to operating cycles. Therefore, there is often an effort to accelerate testing by increasing the severity of one or more environmental factors, such as temperature, concentration, aeration, and pH. Care must be taken that the altered conditions do not give spurious results. For example, an excessive temperature may either introduce a new failure mode or prevent a failure mode relevant to the actual application. The effects of minor constituents or impurities on corrosion are of special concern in simulated testing.

Pitting and crevice corrosion are readily tested in the laboratory by using small coupons and controlled-temperature conditions. A procedure for such tests using 6% FeCl₃ (10% FeCl₃ · 6H₂O) is described in ASTM G 48 (Ref 57). This procedure is performed in 3 days. The coupon may be evaluated in terms of weight loss, pit depth, pit density, and appearance. Several suggestions for methods of pitting evaluation are given in ASTM G 46 (Ref 58). Reference 57 also describes the construction of a crevice corrosion coupon (Fig. 20). It is possible to determine a temperature below which crevice corrosion is not initiated for a particular material and test environment. This critical crevice temperature (CCT) provides a useful ranking of stainless steels. For the CCT to be directly applicable to design, it is necessary to determine that the test medium and conditions relate to the most severe conditions to be encountered in service.

Fig. 20 Assembled crevice corrosion test specimen. Source: Ref 59

Figure 21 shows one of several frequently used specimens with a multiple-crevice assembly. The presence of many separate crevices helps to deal with the statistical nature of corrosion initiation. The severity of the crevices can be regulated by means of a standard crevice design and the use of a selected torque in its application.

Fig. 21 Multiple-crevice cylinders for use in crevice corrosion testing. Source: Ref 59

Laboratory media do not necessarily have the same response of corrosivity as a function of temperature as do engineering environments. For example, the ASTM G 48 solution is thought to be roughly comparable to seawater at ambient temperatures. However, the corrosivity of FeCl_3 increases steadily with temperature. The response of seawater to increasing temperature is quite complex, relating to such factors as concentration of oxygen and biological activity. Also, the various families of stainless steels will be internally consistent, but will differ from one another in response to a particular medium.

Pitting and crevice corrosion may also be evaluated by electrochemical techniques. When immersed in a particular medium, a metal coupon will assume a potential that can be measured relative to a standard reference electrode. It is then possible to impress a potential on the coupon and observe the corrosion as measured by the resulting current. Various techniques of canning the potential range provide extremely useful data on corrosion resistance. Figure 22 demonstrates a simplified view of how these tests may indicate the corrosion resistance for various materials and media.

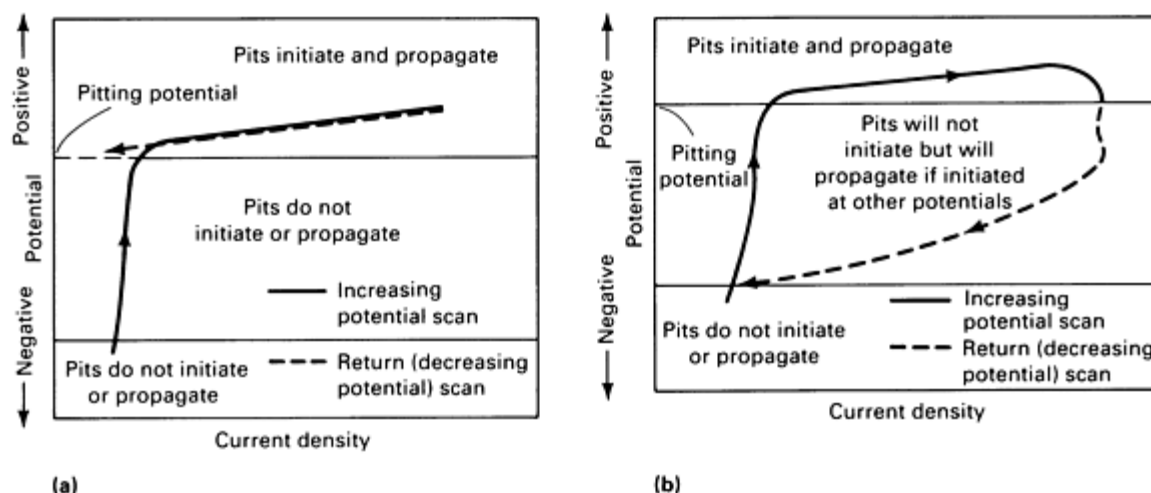

Fig. 22 Schematics showing how electrochemical tests can indicate the susceptibility to pitting of a material in a given environment. (a) Specimen has good resistance to pitting. (b) Specimen has poor resistance to pitting. In both cases, attack occurs at the highest potentials. Source: Ref 59

The nature of intergranular sensitization has been discussed earlier in this article in the section "Forms of Corrosion in Stainless Steels." There are many corrosion tests for detecting susceptibility to preferential attack at the grain boundaries. The appropriate media and test conditions vary widely for the different families of stainless steels. Table 29 summarizes the ASTM tests for intergranular sensitization. Figure 23 shows that electrochemical techniques may also be used, as in the electrochemical potentiostatic reactivation (EPR) test.

Table 29 ASTM standard tests for susceptibility to intergranular corrosion in stainless steels

ASTM test method	Test medium and duration	Alloys	Phases detected
A 262, practice A	Oxalic acid etch; etch test	AISI types 304, 304L, 316, 316L, 317L, 321, 347 casting alloys	Chromium carbide

Stress-corrosion cracking covers all types of corrosion involving the combined action of tensile stress and corrodent. Important variables include the level of stress, the presence of oxygen, the concentration of the corrodent, temperature,

and the conditions of heat transfer. It is important to recognize the type of corrodent likely to produce cracking in a particular family of steel. For example, austenitic stainless steels are susceptible to chloride SCC (Table 30). Martensitic and ferritic grades are susceptible to cracking related to hydrogen embrittlement.

(a) U-bend tests, stressed beyond yielding.

(b) Fails, cracking observed.

(c) Passes, no cracking observed.

(d) Susceptibility of grade to SCC determined by variation of composition within specified range.

(e) Susceptibility of grade to SCC determined by variation of thermal history.

It is important to realize that corrosion tests are designed to single out one particular corrosion mechanism. Therefore, determining the suitability of a stainless steel for a particular application usually requires consideration of more than one type of test. No single chemical or electrochemical test has been shown to be an all-purpose measure of corrosion resistance. More information on corrosion testing is available in the Section "Corrosion Testing and Evaluation" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Surface Finishing of Stainless Steel

Stainless steels have the capability of maintaining bright finished surfaces in many ambient environments. Lacquers and other protective coatings are seldom recommended, because unprotected stainless steel surfaces are more serviceable and easier to clean than coated surfaces. (Stainless steels may be painted provided that their surfaces are first chemically cleaned or etched, or both, for good paint adherence.) Any of several surface textures and degrees of finish can be specified, depending on the particular requirements of the application.

After fabrication, stainless steels may be bright finished by any of the following methods: mechanical grinding and polishing, Tampico brushing, buffing, electrolytic polishing, barrel finishing, or wet or dry blasting (see the article "Surface Engineering of Stainless Steels" in *Surface Engineering*, Volume 5 of *ASM Handbook* for detailed information). Sometimes, two or more of these methods are used in combination. In addition, and of several processes that involve combinations of heating and chemical treatment can be used to produce dull black surface having good abrasion resistance; this is done most often on small parts. The most widely used finishing process, however, is grinding or grinding and polishing.

When fabrication does not involve extensive machining, severe deformation, or general surface marring, sheet and round bar are often polished before fabrication. Welds in prepolished parts may be finished by grinding the welds flush and then polishing contrasting stripes over the weld seams. Alternatively, the entire surface may be given a final polish in the direction of previous polishing to render weld area virtually invisible.

Grinding, Polishing, and Buffing. The term grinding applies to rough, often dry, finishing operations in which significant amounts of metal are removed using loose abrasives or abrasive belts coarser than 100 grit. Polishing refers to finishing operations using abrasives finer than 100 grit suspended in lubricants. Buffing is a special type of polishing that is done with high-speed cloth wheels charged with extremely fine abrasives.

Although equipment used for grinding and polishing stainless steel is the same as standard equipment used for grinding and polishing other metals, the characteristics of stainless steel necessitate some modifications in technique. The suggestions given below for austenitic chromium-nickel types apply to straight-chromium types as well, even though the latter have certain characteristics similar to those of carbon steels. Variations in procedure may be necessary because of differing characteristics of the various types. The chromium-nickel types have about half the thermal conductivity and nearly twice the coefficient of expansion of carbon steels. This combination of characteristics means that austenitic stainless steels tend to heat up locally when ground or polished. When this occurs, they expand excessively in the heated area. It is very important, therefore, that polishing heads not be allowed to dwell on one spot, and excessive polishing pressure should be avoided. Attempts to hasten polishing will aggravate overheating and may cause the part to warp or buckle.

Straight-chromium stainless steels tend to load the abrasive, and this can result in scoring or galling of the polished surface. Frequently, chromium stainless steel appears slightly rougher than chromium-nickel stainless steel when the same polishing grits have been used. A slight color difference exists between polished finishes on chromium and those on chromium-nickel types, although this difference is not usually noticeable, unless pieces are adjacent and in the same general viewing plane.

Polishing in different directions in different areas of the same surface produces contrasts in appearance. A pleasing contrast can be obtained by polishing one area in a direction perpendicular to the polishing direction for another area. However, there sometimes is little or no contrast when different areas are polished in directions opposite (180 °) to each other. If uniformity is desired, grit lines should be parallel over the entire surface; long, even strokes are required when hand tools are used.

Buffing, when used to produce a fine, scratch-free, mirror finish, usually consists of two operations: the cutting operation, in which a high wheel speed and a cutting compound are used; and the coloring operation, in which a slightly lower wheel speed and a color compound are employed. A satin finish, which is really the result of fine polishing rather than a true buffed finish, is produced by final buffing with satin finish compounds. Usually, grinding and polishing are necessary to obtain a surface suitable for buffing.

Grinding of welds using solid grinding wheels of suitable grit will remove excess weld metal and prepare weld surfaces for subsequent polishing operations. Welds should be ground in the direction of the weld bead without allowing the wheel to dwell in one spot. Grinding across the weld is objectionable, because cross grinding tends to cut into parent

metal surfaces. Small-diameter wheels are controlled more easily than large-diameter wheels. It is advisable to stop rough grinding before the weld reinforcement is entirely removed, thereby leaving some stock for finishing. When only one surface of a weld must be finished, the side opposite that from which the weld was made usually has less surplus metal and requires less grinding. Light-gage sheet or strip should be rigidly backed up to provide a firm base for grinding.

Subsequent polishing and buffing can then be done in the usual manner. Where feasible, welds in mill-polished sheet should run in the direction of the polishing lines. This makes it easier to polish the weld to match the existing finish.

Electropolishing provides, at low cost, the combination of an attractive high-luster finish plus deburring. In electropolishing, which is the reverse of electroplating, a small amount of surface metal is removed. Wire and bar products, stampings, and small forgings have been electropolished with good results. Recesses in intricately shaped pieces may be readily brightened, making electropolishing particularly suitable for springs, wire racks, and the inside surfaces of deep-drawn bowls and pans.

Because it removes only a small amount of metal, electropolishing does not eliminate heavy scratches, deep die scoring, or embedded nonmetallic particles. The process is not recommended for descaling, although it removes discoloration such as that resulting from spot welding. An electropolishing finish does not simulate a mechanically polished finish.

Mill Finishes

Sheet strip plate, bar, and wire made of stainless steel all have different designations of mill finish, each, representing a standardized appearance that is characteristic of the process used to impart final mechanical properties. Although the various mill finishes are standardized, there is sufficient variability in mill processing that exact matching of color and reflectivity cannot be expected from lot to lot. Even wider differences can be expected between mill products from different producers.

Sheet finishes are designed by a system of numbers: No. 1, 2D, 2B, and 2BA for unpolished finishes; and No. 3, 4, 6, 7, and 8 for polished finishes.

Each of the unpolished finishes is in itself a category of finishes, with variations in appearance and smoothness, depending on composition, sheet thickness, and method of manufacture. Generally, the thinner the sheet, the smoother the surface. Chromium-nickel and chromium-nickel-manganese stainless steel are characteristically different in appearance from straight-chromium types having the same finish. Furthermore, sheet produced continuously (in coil form) generally differs in appearance from sheet produced as individual pieces on hand mills.

The appearance or "color" of polished finishes may differ slightly among 2xx-, 3xx-, and 4xx-series stainless steels. Sheet can be produced with one or both sides polished; when only one side is polished, the other side is often rough ground to obtain better flatness.

No. 1 finish is produced by hot rolling followed by annealing and descaling. It is generally used in industrial applications where smoothness of finish is not particularly important, such as equipment for elevated-temperature or corrosion service.

No. 2D finish is a dull cold-rolled finish produced by cold rolling, annealing, and descaling. The dull finish may result from descaling or pickling or it may be developed by a final light cold rolling pass using dull rolls. No. 2D finish is favorable for retention of lubricants in deep drawing and is generally preferred for deep-drawn articles that will be polished after fabrication.

No. 2B finish is a bright cold-rolled finish commonly produced in the same manner as No. 2D, except that the final light cold rolling pass is done using polished rolls. No. 2B is a general-purpose cold-rolled finish commonly used for all but exceptionally difficult deep-drawing applications. It is more readily polished to a high luster than is a No. 1 or No. 2D finish.

No. 2BA finish is a mirrorlike appearance produced by cold rolling, followed by bright annealing or double bright annealing. The final appearance is developed by a single light skin pass through a cold mill over highly polished rolls, but is dependent on additional millwork, such as grinding of the surface at an intermediate gage. A No. 2BA finish is often specified for architectural applications and for other uses where a highly reflective surface is desired on the as-fabricated part.

No. 3 finish is a polished finish obtained with abrasives approximately 100 mesh in particle size. It is used for articles that may or may not receive additional polishing during fabrication.

No. 4 finish is a general-purpose polished finish widely used for restaurant equipment, kitchen equipment, storefronts, and dairy equipment. Following initial grinding with coarser abrasives, final finishing is generally done with abrasives having a particle size of approximately 120 to 150 mesh.

No. 6 finish is a dull finish having lower reflectivity than No. 4 finish. It is produced by Tampico brushing No. 4 finish sheet in a medium of abrasive and oil. It is used in architectural and ornamental applications where high luster is undesirable or for contrast with brighter finishes.

No. 7 finish has a high degree of reflectivity. It is produced by buffing finely ground surfaces, but not to the extent that existing grit lines are removed. It is used chiefly for architectural and ornamental parts.

No. 8 finish, the most reflective finish that is commonly produced on sheet, is obtained by polishing with successively finer abrasives and buffing extensively with very fine buffing rouges. The surface is essentially free of grit lines from preliminary grinding operations. No. 8 finish is most widely used for press plates, small mirrors, and reflectors.

Strip Finishes. Only three unpolished finishes (No. 1, No. 2, and bright annealed) and one polished finish (mill buffed) are commonly supplied on stainless steel strip. As with finishes on stainless steel sheet, each unpolished strip finish comprises a category of finishes that vary in appearance and smoothness depending on composition, thickness, and method of manufacture. Generally, the thinner the strip, the smoother the surface. Chromium-nickel and chromium-nickel-manganese stainless steels are characteristically different in appearance from straight-chromium types having the same finish.

No. 1 finish is produced by cold rolling, annealing, and pickling. Appearance varies from dull gray matte to fairly reflective, depending largely on stainless steel type. This finish is used for severely drawn or formed parts, as well as for applications where the brighter No. 2 finish is not required, such as parts to be used at high temperatures. No. 1 finish for strip approximates No. 2D finish for sheet in corresponding chromium-nickel or chromium-nickel-manganese types.

No. 2 finish is produced by the same treatment used for No. 1 finish, followed by a final light cold rolling pass, which is generally done using highly polished rolls. This final pass produces a smoother and more reflective surface, the appearance of which varies with stainless steel type. No. 2 finish for strip is a general-purpose finish widely used for household appliances, automotive trim, tableware, and utensils. No. 2 finish for strip approximates No. 2B finish for sheet in corresponding chromium-nickel or chromium-nickel-manganese stainless steels.

Bright annealed finish is a bright, cold-rolled, highly reflective finish retained by final annealing in a controlled-atmosphere furnace. The purpose of atmospheric control is to prevent scaling or oxidation during annealing. The atmosphere usually consists of either dry hydrogen or dissociated ammonia. Bright annealed strip is used most extensively for automotive trim.

Mill-buffed finish is a highly reflective finish obtained by subjecting either No. 2 or bright annealed coiled strip to a continuous buffing pass. The purpose of mill buffing is to provide a finish uniform in color and reflectivity. It also can provide a surface receptive to chromium plating. This type of finish is used chiefly for automotive trim, household trim, tableware, utensils, fire extinguishers, and plumbing fixtures.

Plate Finishes. Stainless steel plate can be produced in a variety of conditions and surface finishes:

Condition and Finish	Description and remarks
Hot rolled	Scale not removed; not heat treated; plate not recommended for final use in this condition^(a)
Hot or cold rolled, annealed or heat treated	Scale not removed; use of plate in this condition generally confined to heat-resisting applications; scale impairs corrosion resistance^(a)
Hot or cold rolled, annealed or heat treated, blast cleaned or pickled	Condition and finish commonly preferred for corrosion-resisting and most heat-resisting applications
Hot or cold rolled, annealed, descaled and temper passed	Smoother finish for specialized applications
Hot rolled, annealed, descaled, cold rolled, annealed, descaled, optionally temper passed	Smooth finish with greater freedom from surface imperfections than any of the above
Hot or cold rolled, annealed or heat treated, surface cleaned and polished	Polished finishes similar to the polished finishes on sheet

(a) Surface inspection is not practicable for plate that has not been pickled or otherwise descaled.

Plate is often conditioned by localized grinding to remove surface imperfections on either one or both surfaces; ground areas are well flared, and the thickness is not reduced below the allowable tolerance in any of these areas.

Bar Finishes. Stainless steel bar is produced in a number of conditions and surface finishes (it is important that both condition and finish be specified, because each finish is applicable only to certain conditions):

Condition	Surface finish
Hot worked only	Scale not removed (except for spot conditioning)
	Rough turned^{(a)(b)}
	Blast cleaned
Annealed or otherwise heat treated	Scale not removed (except for spot conditioning)
	Rough turned^(a)
	Pickled or blast cleaned and pickled

	Cold drawn or cold rolled
	Centerless ground^(a)
	Polished^(a)
Annealed and cold worked to high tensile strength ^(c)	Cold drawn or cold rolled
	Centerless ground^(a)
	Polished^(a)

(a) Applicable to round bar only.

(b) Bar of 4xx series stainless steels that are highly hardenable, such as types 414, 420, 420F, 431, 440A, 440B and 440C, are annealed before rough turning. Other hardenable types, such as types 403, 410, 416, and 416Se, also may require annealing depending on composition and size.

(c) Produced only in mill orders; made predominantly in types 301, 302, 303Se, 304, 304N, 316, and 316N

Wire Finishes. Finishes used on wires can be classified as:

- Oil drawn or grease drawn
- Diamond drawn
- Copper coated
- Tinned
- Lead coated

Oil- or grease-drawn finish is a special bright finish for wire intended for uses, such as racks and handles, where the finish supplied is to be the final finish of the end product. In producing this finish, lower drawing speeds are necessary, and additional care in processing is needed to provide a surface with few scratches and with only a very light residue of lubricant.

Diamond-drawn finish is a very bright finish generally limited to wet-drawn stainless steel wire in fine sizes. Drafting speeds are necessarily reduced to obtain the desired brightness.

Copper-coated wire is supplied when a special finish is required for lubrication in an operation such as spring coiling or cold heading. Generally, copper-coated wire is drawn after coating, the amount depending on the desired cold-worked temper of the wire.

Tinned wire is coated by passing single strands through a bath of molten tin. Tinned wire is used in soldering applications. The temper of the finished wire is controlled by processing prior to tinning.

Lead-coated wire is coated by passing single strands through, or immersing bundles of wire in, a bath of molten lead. The wire is then drawn to final size, with the lead forming a thin coating over the entire surface. This coating is useful on wire for coil springs, where it serves as a lubricant during coiling operations.

Interim Surface Protection

Finishes on stainless steel often require protection during shipment of mill products to fabrication plants. Otherwise, it is inevitable that scratches, dings, and other evidence of material-handling operations will mar the appearance of some end products. Furthermore, if a mill finish is intended to give the end product its appearance, the finish must be protected from incidental damage during fabrication of parts. Although finishes on completed parts and assemblies can be protected by proper packaging, such packaging can be made much simpler in design if the need to protect the finish from certain kinds of incidental damage during shipment can be reduced.

All of these considerations have led to the development of various masking materials for the protection of finishes on stainless steel surfaces prior to end use. Masking materials used in mills are most often obtained in the form of rolls of adhesive-backed protective film that can be applied by hand or machine to stainless steel mill products. In addition, water-base and solvent-base strippable coatings are available; these are applied by dip-dry methods. Sometimes, special adhesive-backed protective coverings of the customer's choosing can be applied at the mill prior to shipment.

Most often, adhesives are based on latex or proprietary organic compounds. Masking materials include paper, rubber, and plastics. Plastics such as polyvinyl chloride, polyolefin, polyethylene, and polypropylene are the most popular. Coverings range in thickness from about 0.06 to 0.13 mm (2.5 to 5 mils) and are available in several colors (generally white, clear, black, and light blue). Sometimes, paper coverings are printed with a company logo or a proprietary message such as instructions for in-service care of the finish.

Adhesion to stainless steel is generally measured as the force per unit width required to remove the covering from sheet having a No. 4 finish. Other data available from the masking material manufacturer include tensile strength, elongation, and unwinding force.

Plastic and rubber coverings have sufficient elongation and adhesion to enable them to survive all but the most severe fabrication operations, including drawing, bending, and roll forming.

Of interest to the end-user, of course, is the ease with which the masking material can be removed. Often, a compromise must be reached between the degree of protection afforded the finish and the ease of removal. Usually, adhesive-backed coverings are easiest to remove when the coated steel is first received. They often become more difficult to remove if they are exposed to temperatures significantly above or below normal room ambient, to ultraviolet light, or to outdoor (weathering) environments. Excessively prolonged indoor storage can also make it quite difficult to remove adhesive-backed coverings.

In-Service Care

Despite the fact that stainless steel surfaces are generally considered nontarnishing, they still need a certain amount of care to maintain a given surface appearance under normal conditions of service. Table 31 summarizes methods of cleansing stainless steel for a wide variety of applications.

Table 31 Typical methods of cleansing stainless steel surfaces

Cleansing problem	Cleansing agent ^(a)	Method of application ^(b)
Routine cleansing	Soap, ammonia, detergent, water	Sponge with cloth, then rinse with clear water and wipe dry. Satisfactory for use on all finishes
Smears and fingerprints	Arcal 20, Lac-O-Nu, Lumin Wash, O'Cedar Cream Polish, Stainless Shine, Wind-O-Shine	Rub with cloth as directed on the package. Satisfactory for use on all finishes. Provides barrier film to minimize prints
Stubborn spots, stains, and other light discolorations	Allchem Concentrated Cleaner, Samae, Cameo Copper Cleaner, Cooper's Stainless Steel Cleaner, Revere Stainless Steel Cleaner, Paste NuSteel, DuBois Temp, Aerogroom	Apply with sponge or cloth. Satisfactory for use on all finishes. Use in direction of polish lines on No. 4 finish. Use light pressure on No. 2, 7, and 8 finishes. May scratch No. 2, 7, and 8 finishes
	Household cleansers such as Old Dutch, Bab-O, Sapolio, Bon Ami, Ajax, Comet; grade F Italian pumice, Steel Bright, Lumin Cleaner, Zud, Restoro, Sta-Clean, Highlite, Penny-Brite, Copper-Brite, DuBois Stainless Steel Polish	
Burnt-on foods and grease, fatty acids, milk-stone (where swabbing or rubbing is not practical)	Easy-Off, De-Grease-It, 4-6% hot solution of such agents as trisodium phosphate or sodium tripolyphosphate, 5-15% caustic soda solution	Apply generous coating, allow to stand for 10-15 min, rinse. Repeated application may be necessary. Satisfactory for use on all finishes
Tenacious deposits, rusty discolorations, industrial atmospheric stains	Oakite No. 33, Dilac, Flash-Flenz, Caddy Cleaner, Turco Scale 4368, Permag 57	Swab and soak with clean cloth, let stand 15 minutes or more according to directions on package, then rinse and dry. Satisfactory for use on all finishes
Hard-water spots and scale	Vinegar, 5% oxalic acid, 5% sulfamic acid, 5-10% phosphoric acid, Dilac, Oakite No. 33, Texo 12	Swab or soak with cloth, let stand 10-15 min. Always follow with neutralizer rinse and dry. Satisfactory for use on all finishes
Grease and oil	Organic solvents, detergents, caustic cleaners	Rub with cloth. (Organic solvents may be flammable and/or toxic.) Satisfactory for use on all finishes

(a) Use of proprietary names is intended to indicate type of cleanser and does not constitute an endorsement. Omission of any proprietary cleanser does not imply inadequacy. All products should be used in strict accordance with instructions on package.

(b) In all applications, stainless steel wool, a sponge, or a fibrous brush or pad is recommended for scouring stainless steel. Use of ordinary steel wool or steel brushes will leave a residue and result in corrosion and/or rust staining.

Architectural Applications. For exposed exterior surfaces in inland, light industrial areas, minimum maintenance is needed. Ordinarily, normal rainfall is adequate to maintain the desired appearance, and only sheltered areas such as entryways need occasional washing with a scrub brush or a pressurized stream of water. In marine atmospheres and heavy industrial areas, periodic cleaning with detergents and water to remove salt and dirt deposits is advisable. Heavy or stubborn deposits may have to be removed with strong industrial cleaners.

For interior surfaces, only occasional cleaning with detergent and water is required for maintenance of finish. Where fingerprints are a problem, a commercial glass cleaner or wax is suggested. Often, a No. 4 sheet finish is specified to minimize the effect of fingerprints on appearance.

Food-Handling Applications. Stainless steel is widely specified for food-handling equipment because of its excellent bacterial cleanability. In many instances, strong sanitizing sterilizing solutions are used for cleaning the equipment to prevent bacterial contamination of the food products being processed. Where this is done, it should be standard practice to monitor exposure time and thoroughly flush the cleaned surfaces with water. Burnt-on foods and grease spots can be removed by soaking in hot water and detergent. Stubborn spots can be removed by scrubbing with a nonabrasive cleanser and a fiber brush, a sponge, or a pad of stainless steel wool or nickel-silver wool.

Chemical, textile, and drug applications often require high purity in the product being processed. Stainless steel is used in equipment for these industries not only because it is chemically inert to the products, which effectively eliminates corrosion as a possible source of low-level contamination, but also because the surfaces of stainless steel equipment are easy to clean and sterilize, which effectively eliminates bacteria and residues as sources of contamination. Equipment is usually cleaned with strong chemical cleaners and then repeatedly rinsed with water. To facilitate cleaning, equipment usually has rounded corners and fillets, welded construction is used instead of mechanical seams, and all welds and other protrusions are ground flush and polished.

Wrought Stainless Steels

Revised by S.D. Washko and G. Aggen, Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation

Fabrication Characteristics

Wrought stainless steels come from the melting furnaces in the form of either ingot or continuously cast slabs. Ingots require a roughing or primary hot working, which the other form commonly bypasses. All then go through fabricating and finishing operations such as hot and cold forming, welding, rolling, machining, spinning, and polishing. No stainless steel is excluded from any of the common industrial processes because of its special properties; yet all stainless steels require certain modifications of technique.

Hot working is influenced by the heat-resisting characteristic of many of the stainless steels. These alloys are stronger at elevated temperatures than ordinary steel. Therefore they require greater roll and forge pressure, and perhaps lesser reductions per pass or per blow. The austenitic steels are particularly heat resistant.

Machining and forming processes are adaptable to all grades, with these major precautions: First, the stainless steels are generally stronger and tougher than carbon steel, so that more power and rigidity are needed in tooling. Second, the powerful work-hardening effect gives the austenitic grades the property of being instantaneously strengthened upon the first touch of the tool or pass of the roll. Machine tools must therefore bite surely and securely, with care taken to ensure that they do not ride the piece. Difficult forming operations warrant careful attention to variations in grade and in heat treatment to accomplish end purposes without unnecessary working problems. Spinning, for example, has a type 305 modification of 18-8 that greatly favors the operation: at the opposite extreme is type 301 or 17-7, when strengthening due to cold working is an advantage.

Welding is influenced by another aspect of the high-temperature resistance of these metals: the resistance to scaling. Oxidation during service at high temperatures does not become catastrophic with most stainless steel because the steel immediately forms a hard and protective scale. However, this means that welding must be conducted under conditions that protect the metal from such reactions with the environment. This can be done with specially prepared coatings on electrodes, under cover of fluxes, using shielding gas, or in a vacuum.

Sheet Formability

Stainless steels are blanked, pierced, formed, and drawn in basically the same press tools and machines as those used for other metals. However, because stainless steels have higher strength and are more prone to galling than low-carbon steels and because they have a surface finish that often must be preserved, the techniques used in the fabrication of sheet metal

parts from stainless steels are more exacting than those used for low-carbon steels. In contrast to carbon steels, stainless steels usually have:

- Greater strength
- Greater susceptibility to work hardening
- Higher propensity to weld or gall to tooling
- Lower heat conductivity

General ratings of the relative suitability of the commonly used austenitic, martensitic, and ferritic types of stainless steels to various methods of forming are given in Table 32. These ratings are based on formability and on the power required for forming.

Table 32 Relative suitability of stainless steels for various methods of forming

Suitability ratings are based on the comparison of steels within any one class; therefore, it should not be inferred that a ferritic steel with an A rating is more formable than an austenitic steel with a C rating for a particular method. Ratings are A, excellent; B, good; C, fair; D, not generally recommended

Steel	0.2% yield strength, 6.89 MPa (1 ksi)	Suitability for:

(a) Severe sharp bends should be avoided.

As Table 32 shows, the austenitic and ferritic steels are, almost without exception, well suited to all of the forming methods listed. Of the martensitic steels, however, only types 403, 410, and 414 are generally recommended for cold-forming applications. Because the higher carbon content of the remaining martensitic types severely limits their cold formability, these steels are sometimes formed warm. Duplex types have properties intermediate between those of typical austenitic and ferritic grades. Warm forming can also be used to advantage with other stainless steels in difficult applications.

The characteristics of stainless steel that affect its formability include yield strength, tensile strength, ductility (and the effect of work hardening on these properties), and the plastic-strain ratio, *r*, value. The composition of stainless steel is also an important factor in formability. Figure 24 compares the effect of cold work on the tensile strength and yield strength of type 301 (an austenitic alloy), types 409 and 430 (both ferritic alloys), and 1008 low-carbon steel sheet.

Fig. 24 Comparison of work-hardening qualities of type 301 austenitic stainless steel, types 409 and 430

ferritic stainless steels, and 1008 low-carbon steel

Formability of Austenitic Types. Type 301 stainless steel has the lowest nickel and chromium contents of the standard austenitic types; is also has the highest tensile strength in the annealed condition. The extremely high rate of work hardening of type 301 results in appreciable increases in tensile strength and yield strength with each increase in the amount of cold working, as measured by cold reduction (Fig. 24). This response to work hardening is particularly important for structural parts, including angles and channel sections, which, after fabrication, are expected to have additional strength and stiffness. On the other hand, for deep-drawing applications, a lower rate of work hardening is usually preferable and can be obtained in the austenitic alloys that have higher nickel contents, notably, types 304, 304L, and 305.

In general, the austenitic alloys are more difficult to form as the nickel content or both the nickel and the chromium contents are lowered, as in type 301. Such alloys show increased work-hardening rates and are less suitable for deep drawing or multiple forming operations. The presence of the stabilizing elements niobium, titanium, and tantalum, as well as higher carbon contents, also exerts an adverse effect on the forming characteristics of the austenitic stainless steels. Therefore, the forming properties of types 321 and 347 stainless steel are less favorable than those of types 302, 304, and 305.

Formability of Ferritic Types. The range between yield strength and tensile strength of types 409 and 430 narrows markedly as cold work increases, as shown in Fig. 24. This response, typical of the ferritic alloys, limits their formability (ductility) in comparison with the austenitic alloys. Nevertheless, types 409 and 430, although lacking the formability of type 302, are widely used in applications that require forming by blanking, bending, drawing, or spinning. One of the most important applications for type 430 stainless steel is in automotive trim or molding. Type 409 stainless steel has found wide acceptance as the material of choice in automotive exhaust systems.

Formability of Duplex Types. Duplex stainless steels have about twice the yield strength of most austenitic stainless steels. Their elongation, toughness, and work-hardening rates are generally intermediate to those of the usual austenitic and ferritic grades.

Duplex stainless steels can be cold formed and expanded. Their higher strength relative to their austenitic counterparts necessitates greater loads in cold-forming operations. Because elongation is lower, they should be formed to more generous radii than fully austenitic materials. Heavily cold-formed ($> \sim 25\%$) sections should be fully annealed and quenched whenever applications to the alloy present the possibility of stress-corrosion cracking in the service environment. Full annealing is conducted in the temperature range of 1010 to 1100 °C (1850 to 2010 °F), followed by a rapid cooling.

Hot forming operations are usually performed in the temperature range of 980 to 1260 °C (1800 to 2300 °F); the preferred temperature range is dictated by the specific alloy composition. The temperature range of about 370 to 925 °C (700 to 1700 °F) should be avoided to preclude the precipitation of such deleterious phases as σ and α' . These phases can adversely affect mechanical properties and corrosion resistance.

Duplex stainless steels, especially in light gages, can be made to exhibit superplastic behavior at elevated temperatures. This property may be used to advantage in certain operations involving the continuous line annealing of strip and sheet.

Comparison With Carbon Steel. The curves for 1008 low-carbon steel are included in Fig. 24 as a reference for the evaluation of stainless steels. The decrease in formability of 1008 steel with cold work appears to fall between that of types 409/430 and that of the more formable type 301. Figure 24 also shows that cold work does not increase the strength of 1008 as rapidly as it does that of type 301 and the ferritic alloys.

Stress-Strain Relationships. Figure 25 shows load-elongation curves for six types of stainless steel: four austenitic (202, 301, 302, and 304), one martensitic (410), and one ferritic (430). The figure also shows that the type of failure in the cup drawing of the austenitic types was different from that of types 410 and 430, as shown in Fig. 25. The austenitic types broke in a fairly clean line near the punch nose radius, almost as though the bottom of the drawn cup were blanked out; types 410 and 430 broke in the sidewall in sharp jagged lines, showing extreme brittleness as a result of the severe cold work.

Fig. 25 Comparison of ductility of six stainless steels and of the types of failure resulting from deep drawing

As suggested by the data in Fig. 25, the power required to form type 301 exceeds that required by the other austenitic alloys. In addition, type 301 will develop maximum elongation before failing. Types 410 and 430 require considerably less power to form, but fail at comparatively low elongation levels.

Power requirements for forming stainless steel, because of the high yield strength, are greater than those for low-carbon steel; generally, twice as much power is used in forming stainless steel. Because the austenitic steels work harden rapidly in cold-forming operations, the need for added power after the start of initial deformation is greater than that for the ferritic steels. The ferritic steels behave much like plain carbon steels once deformation begins, although higher power is also needed to start plastic deformation.

Forgeability

Stainless steels, based on forging pressure and load requirements, are considerably more difficult to forge than carbon or low-alloy steels, primarily because of the greater strength of stainless steels at elevated temperatures and the limitations on the maximum temperatures at which stainless steels can be forge without incurring microstructural damage. Forging load requirements and forgeability vary widely among stainless steels of different types and compositions; the most difficult alloys to forge are those with the greatest strength at elevated temperatures.

Ingot Breakdown. In discussing the forgeability of the stainless steels, it is critical to understand the types of primary mill practices available to the user of semifinished billet or bloom product.

Primary Forging and Ingot Breakdown. Most stainless steel ingots destined for the forge shop are melted by the electric furnace argon-oxygen decarburization process. They usually weigh between 900 and 13,500 kg (2000 to 30,000 lb), depending on the shop and the size of the finished piece. Common ingot shapes are round, octagonal, and fluted; less common ingot shapes include squares. Until recently, all of these ingots would have been top poured. Increasing numbers of producers are switching to the bottom-poured ingot process. This process is slightly more expensive to implement in the melt shop, but it more than pays for itself in extended mold life and greatly improved ingot surface.

Some stainless steel grades used in the aircraft and aerospace industries are double melted. The first melt is done with the electric furnace and argon-oxygen decarburization, and these electrodes are then remelted by a vacuum arc remelting (VAR) or electroslag remelting (ESR) process. This remelting under a vacuum (VAR) or a slag (ESR) tends to give a much cleaner product with better hot workability. For severe forging applications, the use of remelt steels can sometimes be a critical factor in producing acceptable parts. These double-melted ingots are round in shape and vary in diameter from 460 to 915 mm (18 to 36 in.), and in some cases, they weigh in excess of 11,000 kg (25,000 lb). The breakdown of ingots is usually done on large hydraulic presses (13,500 kN, or 1500 tonf). A few shops, however, still use large hammers, and the four-hammer radial forging machine is being used increasingly for ingot breakdown.

Heating is the single most critical step in the initial forging of ingots. The size of the ingot and the grade of the end-product stainless steel dictate the practice necessary to reduce thermal shock and to avoid unacceptable segregation levels. It is essential to have accurate and programmable control of the furnaces used to heat stainless steel ingots and large blooms.

Primary forging or breakdown of an ingot is usually achieved using flat dies. However, some forgers work the ingot down as a round, using V or swage dies. Because of the high hot hardness of stainless steel and the narrow range of working temperatures for these alloys, light reductions, or saddening is the preferred initial step in the forging of the entire surface of the ingot. Saddening is an operation in which an ingot is given a succession of light reductions in a press or rolling mill or under a hammer in order to break down the skin and overcome the initial fragility due to a coarse crystalline structure preparatory to reheating prior to heavier reductions.

After the initial saddening of the ingot surface is complete, normal reductions of 50 to 100 mm (2 to 4 in.) can be taken. If the chemistry of the heat is in accordance with specifications and if heating practices have been followed and minimum forging temperatures observed, no problems should be encountered in making the bloom and other semifinished product.

If surface tears occur, the forging should be stopped, and the workpiece conditioned. Some forgers use hot powder scarfing, but this presents environmental problems. The most common method is to grind out the defect. The ferritic, austenitic, and nitrogen-strengthened austenitic stainless steels can be air cooled, ground, and reheated for reforging. The martensitic and precipitation-hardening grades must be slow cooled and overaged before grinding and reheating. The ingot surface is important, and many producers find it advantageous to grind the ingots before forging to ensure good starting surfaces.

Billet and Bloom Product. Forgers buy bars, billets, or blooms of stainless steel for subsequent forging on hammers and presses. Forged stainless steel billet and bloom products tend to have better internal integrity than rolled product, especially with larger-diameter sections (>180 mm, or 7 in.). Correctly conditioned billet and bloom product should yield acceptable finished forgings if good heating practices are followed and if attention is paid to the minimum temperature requirements. Special consideration must be given to sharp corners and thin sections, because these tend to cool off very rapidly. Precautions should be taken when forging precipitation-hardening or nitrogen-strengthened austenitic grades.

Closed-Die Forgeability. The relative forging characteristics of stainless steels can be most easily depicted through examples of closed-die forgings. The forgeability trends these examples establish can be interpreted in light of the grade, type of part, and forging method to be used.

Stainless steels of the 300 and 400 series can be forged into any of the hypothetical parts illustrated in Fig. 26. However, the forging of stainless steel into shapes equivalent in severity to part 3 may be prohibited by shortened die life (20 to 35% of that obtained in forging such a shape from carbon or low-alloy steel) and by the resulting high cost. For a given shape, die life is shorter in forging stainless steel than in forging carbon or low-alloy steel.

Fig. 26 Three degrees of forging severity. Dimensions given in inches

Forgings of mild severity, such as part 1 in Fig. 26, can be produced economically from any stainless steel with a single heating and about five blows. Forgings approximating the severity of part 2 can be produced from any stainless steel with a single heating and about ten blows. For any type of stainless steel, die life in the forging of part 1 will be about twice that in the forging of part 2.

Part 3 represents the maximum severity for forging all stainless steels and especially those with high strength at elevated temperature, namely, types 309, 310, 314, 316, 317, 321, and 347. Straight-chromium types 403, 405, 410, 416, 420, 430, 431, and 440 are the easiest to forge into a severe shape such as part 3 (although type 440, because of its high carbon content, would be the least practical). Types 201, 301, 302, 303, and 304 are intermediate between the two previous groups.

One forge shop has reported that part 3 would be practical and economical to produce in the higher-strength alloys if the center web were increased from 3.2 to 6.4 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) and if all fillets and radii were increased in size. It could then be forged with 15 to 20 blows and one reheating, dividing the number of blows about equally between the first heat and the reheat.

Hot Upsetting. Stainless steel forgings of the severity represented by hypothetical parts 4, 5, and 6 in Fig. 27 can be hot upset in one blow in a steel die. However, the conditions are similar to those encountered in hot-die forging. First, with a stainless steel, die wear in the upsetting of part 6 will be several times as great as in the upsetting of part 4. Second, die wear for the forming of any shape will increase as the elevated-temperature strength of the alloy increases. Therefore, type 410, with about the lowest strength at high temperature, would be the most economical stainless steel to be formed of any of the parts, particularly part 6. Conversely, type 310 would be the least economical.

Upset Reduction Versus Forging Pressure. The effect of percentage of upset reduction (upset height versus original height) on forging pressure for low-carbon steel and for type 304 stainless steel at various temperatures is shown in Fig. 28. Temperature has a marked effect on the pressure required for any given percentage of upset, and at any given forging temperature and percentage of upset, type 304 stainless requires at least twice the pressure required for 1020 steel.

Fig. 27 Three degrees of upsetting severity

Fig. 28 Effect of upset reduction on forging pressure for various temperatures. Source: Ref 61

The effects of temperature on forging pressure are further emphasized in Fig.(a) 29. These data, based on an upset reduction of 10%, show that at 760 °C (1400 °F) type 304 stainless steel requires only half as much pressure as A-286 (an iron-base heat-resistant alloy), although the curves for forging pressure for the two metals converge at 1100 °C (2000 °F). However, at a forging temperature of 1100 °C (2000 °F), the pressure required for a 10% upset reduction on type 304 is more than twice that required for a carbon steel (1020) and about 60% more than that required for 4340 alloy steel. Differences in forgeability, based on percentage of upset reduction and forging pressure for type 304 stainless steel, 1020, and 4340 at the same temperature (980 °C, or 1800 °F), are plotted in Fig.(b) 29.

Fig. 29 Forging pressure required for upsetting versus (a) forging temperature and (b) percentage of upset reduction. Source: Ref 62

Austenitic stainless steels are more difficult to forge than the straight-chromium types, but are less susceptible to surface defects. Most of the austenitic stainless steels can be forged over a wide range of temperatures above 925 °C (1700 °F) and because they do not undergo major phase transformation at elevated temperature, they can be forged at higher temperatures than the martensitic types (Table 33). Exceptions to the above statements occur when the composition of the austenitic stainless steel promotes the formation of δ -ferrite, as in the case of the 309S, 310S, or 314 grades. At temperatures above 1100 °C (2000 °F), these steels, depending on their composition, may form appreciable amounts of δ -ferrite. Figure 30 depicts these compositional effects in terms of nickel equivalent (austenitic-forming elements) and chromium equivalent. Delta-ferrite formation adversely affects forgeability, and compensation for the amount of ferrite present can be accomplished with forging temperature restrictions.

Table 33 Typical forging temperature ranges of stainless steels

Stainless steel	Temperature
-----------------	-------------

	°C	°F
More difficult to hot work		
UNS N08020	980-1230	1800-2245

Equally important restrictions in forging the austenitic stainless steels apply to the finishing temperatures. All but the stabilized types (321, 347, 348) and the extralow-carbon types should be finished at temperatures above the sensitizing range (~ 815 to 480°C , or 1500 to 900°F) and cooled rapidly from 870°C (1600°F) to a black heat. The highly alloyed grades, such as 309, 310, and 314, are also limited with regard to finishing temperature, because of their susceptibility at lower temperatures to hot tearing and σ formation. A final annealing by cooling rapidly from about 1065°C (1950°F) is generally advised for nonstabilized austenitic stainless steel forgings in order to retain the chromium carbides in solid solution.

Finishing temperatures for austenitic stainless steels become more critical when section sizes increase and ultrasonic testing requirements are specified. During ultrasonic examination, coarse-grain austenitic stainless steels frequently display sweep noise that can be excessive due to a coarse-grain microstructure. The degree of sound attenuation normally increases with section size and may become too great to permit detection of discontinuities. Careful control of forging conditions, including final forge reductions of at least 5%, can assist in the improvement of ultrasonic penetrability.

The stabilized or extralow-carbon austenitic stainless steels, which are resistant to sensitization, are sometimes strain hardened by small reductions at temperatures well below the forging temperature. Strain hardening is usually accomplished at 535 to 650°C (1000 to 1200°F) (referred to as warm working or hot-cold working). When minimum hardness is required, the forgings are solution annealed.

Sulfur or selenium can be added to austenitic stainless steel to improve machinability. Selenium is preferred because harmful stringers are less likely to exist. Type 321, stabilized with titanium, may also contain stringers of segregate that will open as the surface ruptures when the steel is forged. Type 347, stabilized with niobium, is less susceptible to stringer segregation and is the stabilized grade that is usually specified for forgings.

When heating the austenitic stainless steels, it is especially desirable that a slightly oxidizing furnace atmosphere be maintained. A carburizing atmosphere or an excessively oxidizing atmosphere will impair corrosion resistance, either by harmful carbon pickup or by chromium depletion. In types 309 and 310, chromium depletion can be especially severe.

Nitrogen-strengthened austenitic stainless steels are iron-base alloys containing chromium and manganese. Varying amounts of nickel, molybdenum, niobium, vanadium, and/or silicon are also added to achieve specific properties. Nitrogen-strengthened austenitic stainless steels provide high strength, excellent cryogenic properties and corrosion resistance, low magnetic permeability (even after cold work or subzero temperature), and higher elevated-temperature strengths, compared to the 300-series stainless steels. A partial list of these alloys includes:

- UNS S24100 (Nitronic 32) ASTM XM-28. High work hardening while remaining nonmagnetic plus twice the yield strength of type 304 with equivalent corrosion resistance
- UNS S24000 (Nitronic 33) ASTM XM-29. Twice the yield strength of type 304, low magnetic permeability after severe cold work, high resistance to wear and galling compared to standard austenitic stainless steels, and good cryogenic properties
- UNS S21904 (Nitronic 40) ASTM XM-11. Twice the yield strength of type 304 with good corrosion resistance, low magnetic permeability after severe cold working, and good cryogenic properties
- UNS S20910 (Nitronic 50) ASTM XM-19. Corrosion resistance greater than that of type 316L with twice the yield strength, good elevated and cryogenic properties, and low magnetic permeability after severe cold work
- UNS S21800 (Nitronic 60). Galling resistance with corrosion resistance equal to that of type 304 and twice the yield strength and good oxidation resistance

A forgeability comparison, as defined by dynamic hot hardness, is provided in Fig. 31.

Fig. 31 Comparative dynamic hot hardness versus temperature (forgeability) for various ferrous alloys

Martensitic stainless steels have high hardenability to the extent that they are generally air hardened. Therefore, precautions must be taken when cooling forgings of martensitic steels, especially those with high carbon content, in order to prevent cracking. The martensitic alloys are generally cooled slowly to about 595 °C (1100 °F), either by burying in an insulating medium or by temperature equalizing in a furnace. Direct water sprays, such as might be employed to cool dies, should be avoided, because they would cause cracking of the forging.

Forgings of the martensitic steels are often tempered in order to soften them for machining. They are later quench hardened and tempered.

Maximum forging temperatures for these steels are low enough to avoid the formation of δ -ferrite. If δ -ferrite stringers are present at forging temperatures, cracking is likely to occur. Delta-ferrite usually forms at temperatures from 1095 to 1260 °C (2000 to 2300 °F). Care must be exercised to keep the temperature below this level during forging and to avoid rapid metal movement that might result in local overheating. Surface decarburization, which promotes ferrite formation, must be minimized.

The δ -ferrite formation temperature decreases with increasing chromium content, and small amounts of δ -ferrite reduce forgeability significantly. As the δ -ferrite increases above about 15% (Fig. 30), forgeability improves gradually until the structure becomes entirely ferritic. Finishing temperatures are limited by the allotropic transformation, which begins near 815 °C (1500 °F). However, forging of these steels is usually stopped at about 925 °C (1700 °F) because the metal is difficult to deform at lower temperatures.

Sulfur or selenium can be added to type 410 to improve machinability. However, these elements can cause forging problems, particularly when they form surface stringers that open and form cracks. This can sometimes be overcome by adjusting the forging temperature or the procedure. With sulfur additions, it may be impossible to eliminate all cracking of this type. Therefore, selenium additions are preferred.

Ferritic Stainless Steels. The ferritic straight-chromium stainless steels exhibit virtually no increase in hardness upon quenching. They will work harden during forging; the degree of work hardening depends on the temperature and the amount of metal flow. Cooling from the forging temperature is not critical.

The ferritic stainless steels have a broad range of forgeability, which is restricted somewhat at higher temperature because of grain growth and structural weakness and is closely restricted in finishing temperature only for type 405. Type 405 requires special consideration because of the grain-boundary weakness resulting from the development of a small amount of austenite. The other ferritic stainless steels are commonly finished at any temperature down to 705 °C (1300 °F). For type 446, the final 10% reduction should be made below 870 °C (1600 °F) to achieve grain refinement and room-temperature ductility. Annealing after forging is recommended for ferritic steels.

Precipitation-Hardening Stainless Steels. The semiaustenitic and martensitic precipitation-hardening stainless steels can be heat treated to high hardness through a combination of martensite transformation and precipitation. They are the most difficult to forge and will crack if temperature schedules are not accurately maintained. The forging range is narrow, and the steel must be reheated if the temperature falls below 980 °C (1800 °F). They have the least plasticity (greatest stiffness) at forging temperature of any of the classes and are subject to grain growth and δ -ferrite formation. Heavier equipment and a greater number of blows are required to achieve metal flow equivalent to that of the other types.

During trimming, the forgings must be kept hot enough to prevent the formation of flash-like cracks. To avoid these cracks, it is often necessary to reheat the forgings slightly between the finish forging and the trimming operations. Cooling, especially the cooling of the martensitic grades, must be controlled to avoid cracking.

Duplex Stainless Steels. Because of their higher strength, duplex stainless steels are generally stiff when hot worked, relative to many other stainless grades. Rolling and forging equipment must have sufficient power to reduce the material while it is in the temperature range for optimum hot workability. The surface of finished forgings can be optimized by controlling the initial surface, material composition, phase balance, and hot-working temperature. Wrought structures generally produce a better surface after reforging than does cast material after the initial forging operation.

Machinability

Because of the wide variety of stainless steels available, a simple characterization of their machinability can be somewhat misleading. As shown in later sections of this article, the machinability of stainless steels varies from low to very high, depending on the final choice of alloy. In general, however, stainless steels are considered more difficult to machine than other metals, such as aluminum or low-carbon steels. Stainless steels have been characterized as gummy during cutting, showing a tendency to produce long, stringy chips, which seize or form a built-up edge on the tool. This may result in reduced tool life and degraded surface finish. These general characteristics are due to the following properties possessed by stainless steels to varying degrees (Ref 65, 66) (see also the article "Machining of Stainless Steels" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*):

- High tensile strength (Fig. 24)
- Large spread between yield strength (YS) and ultimate tensile strength (UTS) (Fig. 24)
- High ductility and toughness
- High work-hardening rate (Fig. 24)
- Low thermal conductivity (Fig. 32)

Fig. 32 Comparison of thermal conductivities for carbon steel, S30200 austenitic stainless steel, and S43000 ferritic stainless steel. Source: Ref 67

Despite these properties, stainless steels can be machined under the appropriate conditions. In general, more power is required to machine stainless steels than carbon steels, cutting speeds must often be lower, a positive feed must be maintained, tooling and fixtures must be rigid, chip breakers or curlers may be needed on the tools, and care must be taken to ensure good lubrication and cooling during cutting (Ref. 68). These and other practices are discussed in more detail in the sections on individual conventional machining techniques in the article "Machining of Stainless Steels" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Significant differences in machinability exist between different alloy systems and alloy families, including the various free-machining alloys. This section will discuss machinability both within and among the five basic families of stainless steels.

Machinability of Ferritic and Martensitic Alloys. Free-machining ferritic alloys (such as S43020) and annealed, low-carbon, free-machining martensitic alloys (such as S41600) are the easiest to machine of the stainless steels (Ref 66, 69, 70, 71, 72). In fact, their machinability ratings approach and in some cases are comparable to those of certain free-machining carbon steels (Ref 69, 70, 71). The nonfree-machining lower-chromium ferritic alloys (S40500, S43000) and annealed, low-carbon, straight-chromium martensitic alloys (S40300, S41000) are also generally easier to machine than most other nonfree-machining alloys (Ref 69, 70, 71, 72). The higher-chromium ferritic alloys, such as S44600, are considered by some to be somewhat more difficult to machine than the lower-chromium alloys because of gumminess and stringy chips (Ref 73, 74).

Other than the presence or lack of a free-machining additive, the machining characteristics of martensitic stainless steels are influenced by certain variables:

- Hardness level
- Carbon content
- Nickel content
- Phase balance, that is, the percentage of free or δ -ferrite in the martensitic matrix

Increasing the hardness level for a particular alloy results in a decrease in machinability as measured by various criteria (tool life, drillability, and so on) (Ref 66, 72, 75, 76). Within certain limits, however, surface finish can be improved by machining harder material (Ref 72, 75).

In the martensitic grades, machinability decreases as the carbon content increases from S41000 to S42000 to S44004 or from S41600/S41623 to S42020/S42023 to S44020/S44023. With higher carbon levels, there also tends to be a smaller difference in machinability between the corresponding free-machining and nonfree-machining versions. These effects are primarily due to the increasing quantities of abrasive chromium carbides present as carbon level increases in this series of alloys. As a further detriment to machinability, annealed hardness level increases with increasing carbon level (Ref 72, 73, 74, 75).

Nickel content also influences machinability by increasing annealed hardness levels. Consequently, alloys such as S41400 and S43100 will be more difficult to machine than S41000 in the annealed condition (Ref 70, 71).

Changing phase balance has been used to improve the machining characteristics of S41600. It has generally been found that increasing free or δ -ferrite content results in improved machinability, including tool life and surface finish (Ref 72, 75, 76, 77, 78, 79). The introduction of a higher ferrite content also results in a decreasing hardness capability.

Machinability of Austenitic Alloys. The difficulties in machining attributed to stainless steels in general are more specifically attributable to the austenitic stainless steels (Ref 69, 71, 72, 73, 74, 79). Compared to ferritic and martensitic alloys, typical austenitic alloys have a higher work-hardening rate, a wider spread between yield and ultimate tensile strengths, and higher toughness and ductility. When machining austenitic stainless steels, particularly the nonfree-machining alloys, several factors become more pronounced:

- Tools will run hotter, with more tendency to form a large built-up edge
- Chips will be stringier, with a tendency to tangle, making their removal difficult
- Chatter will be more likely if tool rigidity is inadequate or marginal
- Cut surfaces will be work hardened and more difficult to machine if cutting is interrupted or if the feed rate is too low

Because of these factors, the general precautions for machining stainless steels are particularly important for austenitic alloys.

Although there have been differing opinions (Ref 80), a moderate amount of cold work has been regarded as beneficial to the overall machining characteristics of austenitic stainless steels (Ref 72, 74). The cold working reduces the ductility of the material, which results in cutting with a cleaner chip and less tendency for a built-up edge. This produces a better-machined surface finish but with some loss of tool life due to the higher hardness level (Ref 72).

Automatic screw machine testing has shown that the effects of cold working and hardness are variable and may or may not be seen, depending on the type of alloy and the machining conditions. In such testing, tool life has been lowered by an increasing level of cold work for both free-machining (S30300) and nonfree-machining (S30400, S31600) austenitic stainless steels. This effect is shown in Fig. 33 for S30400. On the other hand, there have also been indications under different cutting conditions of an optimum level of tool life at an intermediate level of cold work (Fig. 34).

Fig. 33 Effect of percent cold draft on machinability in a screw machine test for an enhanced-machining version of S30400. Termination is defined as a 0.075 mm (0.003 in.) increase in the diameter of the part being cut.

Fig. 34 Effect of percent cold draft on machinability in a screw machine test for an enhanced-machining version

of S30400. Termination is defined as a 0.075 mm (0.003 in.) increase in the diameter of the part being cut.

Machined surface finish can be improved by an increasing level of cold work for nonfree-machining alloys (S30400, S31600). Figure 35 shows this effect for S31600. A decreasing tendency for tool chatter with increasing cold work has also been seen for these alloys. On the other hand, the use of cold-drawn bar does not consistently benefit the machined surface finish of a free-machining alloy (S30300).

Fig. 35 Effect of percent cold draft on machined surface finish in a screw machine test for an enhanced-machining version of S31600

Additions of manganese or copper can increase the machinability (Fig. 36) and decrease the high work-hardening rate of the lower-alloy austenitic stainless steels (Ref 79, 81, 82, 83, 84). Austenitic free-machining alloys that have additions of manganese and/or copper include S20300, S30310, S30330, and S30431. Although higher alloy content generally reduces the work-hardening rate, it may not necessarily benefit machinability. Highly alloyed austenitic stainless steels, such as S30900, S31000, and N08020, tend to be more difficult to machine (Ref 70, 71).

Fig. 36 Effect of copper and manganese contents on machinability in a drill test for a free-machining chromium-manganese-nickel austenitic stainless steel. Source: Ref 81

Carbon and nitrogen can affect work-hardening rate and will increase the strength and hardness of austenitic stainless steels. Higher levels of either or both elements will decrease machinability (Fig. 37). Consequently, the high-nitrogen austenitic alloys, such as S20910 and S28200, are more difficult to machine than the standard lower-nitrogen austenitic alloys (Ref 70).

Fig. 37 Effect of carbon and nitrogen contents on machinability in a tool life test for a free-machining 18Cr-9Ni-3Mn austenitic stainless steel. Source: Ref 85

Strong carbide/nitride-forming elements, including titanium and niobium, are used in stainless steels such as S32100 and S34700 to prevent grain-boundary carbide, which can reduce intergranular corrosion resistance. However, the carbide/nitride inclusions are abrasive and will increase tool wear (Fig. 38).

Fig. 38 Comparison of tool wear for austenitic stainless steels with (S32100) and without (S30400) titanium carbide inclusions. Source: Ref 86

Machinability of Duplex Alloys. The machinability of duplex stainless steels is limited by their high annealed strength level. Figures 39 and 40 compare the machinability of a duplex alloy, S32950, with that of a high-nitrogen austenitic alloy, S20910, and a conventional austenitic alloy, S31600, in standard (0.004% S) and enhanced-machining (0.027% S) versions. The duplex alloy (S32950) has a hardness level comparable to that of the high-nitrogen austenitic alloy (S20910), but provides better machinability. However, it does not machine as well as either the standard or the enhanced-machining S31600 alloy.

Fig. 39 Comparison of tool life for a duplex stainless steel (S32950), a high-nitrogen austenitic stainless steel (S20910), and a lower-nitrogen austenitic stainless steel (S31600). Tool life is measured as the distance traveled along a 25 mm (1.0 in.) diam bar until tool failure. Shaded areas represent distance to failure.

Fig. 40 Comparison of machinability in a drill penetration test for a duplex stainless steel (S32950), a high-

nitrogen austenitic stainless steel (S20910), and a lower-nitrogen austenitic stainless steel (S31600)

Other nitrogen-bearing duplex alloys are expected to machine similarly to S32950. No enhanced-machining versions of duplex alloys are available.

Machinability of Precipitation-Hardenable Alloys. The machinability of precipitation-hardenable stainless steels depends on the type of alloy and its hardness level. Martensitic precipitation-hardened stainless steels are often machined in the solution-treated condition; therefore, only a single aging treatment is required afterward to reach the desired strength level. In this condition, the relatively high hardness limits machinability. Most of these alloys machine comparably to, or somewhat worse than, a standard austenitic alloy such as S30400. Alloy S17400 is available in enhanced-machining versions that allow machining at higher speeds with a significantly reduced tendency toward chatter.

Martensitic precipitation-hardenable stainless steels can also be machined in an aged condition so that the heat treating can be avoided and closer tolerances maintained. The ease of cutting generally varies with the hardness or heat-treated condition (Table 34).

Table 34 Relative machinability of 17-4 PH (S17400) in various heat-treated conditions

Condition	Typical hardness, HRC
Improved machinability (higher cutting speed)	
H1150M	27
H1150	33
H1075	36
A (solution treated)	34
H1025	38
H900	44
Improved surface finish	

Source: Ref 87

In the annealed, austenitic condition, semiaustenitic alloys can be expected to machine with difficulty, somewhat worse than an alloy such as S30200, which has a high work-hardening rate. Alloys S35000 and S35500 can be supplied in an equalized and overtempered condition, which provides the best machinability. As with the martensitic precipitation-hardenable alloys, machining difficulties increase with aged hardness level.

Austenitic precipitation-hardenable alloys, such as S66286, machine quite poorly, requiring slower cutting rates than even the highly alloyed austenitic stainless steels (Ref 70). Machining in an aged condition requires even slower speeds.

General Guidelines. The characteristics of stainless steels that have a large influence on machinability include:

- Relatively high tensile strength

- High work-hardening rate, particularly for the austenitic alloys
- High ductility

These factors explain the tendency of the material to form a built-up edge on the tool during traditional machining operations. The chips removed in machining exert high pressures on the nose of the tool; these pressures, when combined with the high temperature at the chip/tool interface, cause pressure welding of portions of the chip to the tool. In addition, the low thermal conductivity of stainless steels contributes to a continuing heat buildup.

Figure 41 compares the machinability ratings of selected stainless steels using AISI B1112 as the reference. The difficulties involved in the traditional machining of stainless steels can be minimized by observing the following points:

- Because more power is generally required to machine stainless steels, equipment should be used only up to about 75% of the rating for carbon steels
- To avoid chatter, tooling and fixtures must be as rigid as possible. Overhang or protrusion of either the workpiece or the tool must be minimized. This applies to turning tools, drills, reamers, and so on
- To avoid glazed, work-hardened surfaces, particularly with austenitic alloys, a positive feed must be maintained. In some cases, increasing the feed and reducing the speed may be necessary. Dwelling, interrupted cuts, or a succession of thin cuts should be avoided
- Lower cutting speeds may be necessary, particularly for nonfree-machining austenitic alloys, precipitation-hardenable stainless steels, or higher-hardness martensitic alloys. Excessive cutting speeds result in tool wear or tool failure and shutdown for tool regrinding or replacement. Slower speeds with longer tool life are often the answer to higher output and lower costs
- Tools, both high-speed steel and carbides, must be kept sharp, with a fine finish to minimize friction with the chip. A sharp cutting edge produces the best surface finish and provides the longest tool life. To produce the best cutting edge on high-speed steel tools, 60-grit roughing should be followed by 120- and 150-grit finishing. Honing produces an even finer finish
- Cutting fluids must be selected or modified to provide proper lubrication and heat removal. Fluids must be carefully directed to the cutting area at a sufficient flow rate to prevent overheating

Weldability

The metallurgical features of each group generally determines the weldability characteristics of the steels in that group. The weldability of martensitic stainless steels is greatly affected by hardenability that can result in cold cracking. Welded joints in ferritic stainless steel have low ductility as a result of grain coarsening that is related to the absence of allotropic (phase) transformation. The weldability of austenitic stainless steels is governed by their susceptibility to hot cracking, as is the case with other single-phase alloys with a face-centered cubic (fcc) crystal structure. With the precipitation-

hardening stainless steels, weldability is related to the mechanisms associated with the transformation (hardening) reactions (Ref 89).

Stainless steels can be joined by most welding processes, but with some restrictions. In general, those steels that contain aluminum or titanium, or both, can be arc welded only with the gas-shielded processes. The weld joint efficiency depends upon the ability of the welding process and procedures to produce nearly uniform mechanical properties in the weld metal, heat-affected zone, and base metal in the as-welded or postweld heat-treated condition. These properties can vary considerably with ferritic, martensitic, and precipitation hardening steels (Ref 89).

Weldability and various suitability-for-service conditions, including temperature, pressure, creep, impact, and corrosion environments (see the article "Corrosion of Weldments" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*), require careful evaluation because of the complex metallurgical aspects of stainless steels.

Shielded metal arc (SMAW), submerged arc (SAW), gas metal arc (GMAW), gas tungsten arc (GTAW), and plasma arc welding (PAW) are used extensively for joining stainless steels. Flux cored arc welding (FCAW) is also used, but to a lesser extent. The remainder of the article discusses the weldability of the various grades and the suitability of arc welding processes for specific conditions and requirements.

Austenitic Stainless Steels. Differences in composition among the standard austenitic stainless steels affect weldability and performance in service. For example, types 302, 304, and 304L differ primarily in carbon content, and consequently there is a difference in the amount of carbide precipitation that can occur in the heat-affected zone (HAZ) after the heating and cooling cycle encountered in welding. Types 303 and 303Se contain 0.20% P (max) plus 0.15% Se or S for free machining. These elements are detrimental to weldability and can cause severe hot cracking in the weld metal. Types 316 and 317 contain molybdenum for increased corrosion resistance and higher creep strength at elevated temperatures. However, unless controlled by extralow carbon content, as in type 316L, carbide precipitation occurs in the HAZ during welding. Types 318, 321, 347, and 348 are stabilized with titanium, or niobium-plus-tantalum, to prevent the intergranular precipitation of chromium carbides when the steels are heated to a temperature in the sensitizing range, as during welding.

Welding Characteristics. The austenitic stainless steels, except for the free-machining grades, are the easiest to weld and produce welded joints that are characterized by a high degree of toughness, even in the as-welded condition. Serviceable joints can be readily produced if the composition and the physical and mechanical properties are well suited to the welding process and condition. The heat of welding, contamination, carbide precipitation, cracking, and porosity must be considered before, during, and after welding stainless steels.

Heat of Welding. Excessive heat input may result in weld cracking, loss of corrosion resistance, warping, and undesirable changes in mechanical properties. Welds in stainless steels generally require 20 to 30% less heat input than welds in carbon grades because stainless steels have lower thermal conductivity and higher electrical resistance. Because of low thermal conductivity, heat remains near the weld, so that more heat is available to melt the material, which may produce detrimental results. Excessive heat produces large thermal gradients across the joint, which can cause distortion. Because heat dissipates slowly in stainless steel, it may lower corrosion resistance and change strength. These effects can be minimized with chill bars and less heat input. Weld metal cracking, another problem resulting from excessive welding heat, is discussed later in this article.

The high electrical resistivity of stainless steel makes it suitable for welding with low heat inputs. With reduced heat, good penetration and fusion result because low thermal conductivity retains heat in the weld area. Comparative electrical resistivities are 25 to 50 $\mu\Omega \cdot \text{in.}$ for carbon steel and 175 to 200 $\mu\Omega \cdot \text{in.}$ for austenitic grades. Heat input can be reduced by using low amperages, low voltages (short arc lengths), high travel speeds, and stringer beads. With GMAW and GTAW processes, heat input can be affected by the type of shielding gas. Argon produces a cool, stable arc, while helium produces a hot arc that is somewhat unstable. For manual processes, pure argon is generally best. When working with automatic welding equipment that offers good control of amperage, voltage, and travel speed, mixed gases can be used without risking damage from high heat. Finally, pulsed arc welding techniques can be used to lower heat input.

Weld Contamination. Contaminants not only hinder successful welding, but may prevent an apparently sound weld from functioning satisfactorily. A contaminated weld has inferior corrosion resistance and strength, and the weldment may fail prematurely. The stainless steel itself may also contain the contaminant. Free-machining stainless steels frequently contain sulfur or selenium. Both elements can make the steel unweldable. Similarly, high concentrations of carbon in high-strength stainless steel can inhibit weld serviceability.

External sources of contamination include carbon, nitrogen, oxygen, iron, and water. Carbon is often picked up from shop dirt, grease, forming lubricants, paint, marking materials, and tools; consequently, steel parts should be cleaned before welding and during welding. Otherwise, carbon contamination can cause welds to crack, change the mechanical properties, and lower the corrosion resistance in weld areas. Although iron contamination generally does not affect weldability, it can lower serviceability. Flakes of iron on surfaces rust, thereby speeding localized corrosion. The welder may unknowingly cause the contamination by grinding stainless steel with a wheel previously used on carbon steel. Clean Al_2O_3 grinding wheels, preferably those not used for grinding other alloys, should be used.

One of the most troublesome types of contamination is stainless steel surface contamination by copper, bronze, lead, or zinc from hammers, hold-down fingers on seamers, or tools used in fabrication. Small amounts of these materials on the surface of the stainless steel can lead to cracking in the high-temperature HAZ of the weld. This type of cracking generally occurs in the HAZ, where the contaminant attacks the grain boundaries.

Effect of Carbide Precipitation on Corrosion Resistance of Welded Joints. The precipitation of intergranular chromium carbides is accelerated by an increase in temperature within the sensitizing range and by an increase in time at temperature. When intergranular chromium carbides are precipitated at welded joints, resistance to intergranular corrosion and stress corrosion markedly decreases. The decrease in corrosion resistance is attributed to the presence of the chromium-rich carbides at the grain boundaries and the depletion of chromium in the adjacent matrix material. Although intergranular carbide precipitation generally occurs between 425 and 870 °C (800 and 1600 °F), sensitization is restricted to a narrow range by the fairly rapid heating and cooling that usually occur in welding. The narrower range varies with time at temperature and steel composition, but is approximately 650 to 870 °C (1200 to 1600 °F).

The base metal immediately adjacent to the weld is annealed or solution treated by the heat of welding and, because it generally is cooled rapidly enough to hold the dissolved carbides in solution, this zone usually exhibits normal resistance to corrosive attack. A short distance from the weld, about 3.2 mm ($\frac{1}{8}$ in.) (the distance depending on the thermal cycle and material thickness), there is a narrow zone in which lower heating and cooling rates prevail. In this HAZ, intergranular precipitation of chromium carbides is most likely to take place. Harmful carbide precipitation can be overcome or prevented by the use of:

- Postweld solution annealing
- Extralow-carbon, that is, 0.03% C (max), alloy
- Stabilized alloy containing preferential carbide-forming elements, such as niobium-plus-tantalum or titanium

Solution annealing puts carbides back into solution and restores normal corrosion resistance, but is generally inconvenient. The solution-annealing temperature range is very high, 1040 °C (1900 °F) minimum, and unless stainless steel is protected from air at these temperatures, it oxidizes rapidly, forming adherent oxide scale. Thin sections, unless adequately supported, may sag or be severely distorted at these temperatures or during rapid cooling from them. Rapid cooling in solution annealing may present other problems. Water quenching, although effective, is seldom feasible except for small workpieces of simple shape. Unless adequate safeguards are available, water quenching of large workpieces from the solution-annealing temperature is hazardous. Often solution annealing is impractical because the workpiece is too large for available furnace and cooling facilities.

Extralow-carbon stainless steels (types 304L and 316L) are resistant to carbide precipitation in the 425 to 870 °C (800 to 1600 °F) range and can thus undergo normal welding without reduction in corrosion resistance. Carbides precipitate in significant quantities when extralow-carbon steels are heated and held in the sensitizing temperature range for an extended period, as in service. These steels are generally recommended for use below 425 °C (800 °F).

Stabilized Steels. Compared with the extralow-carbon steels, the stabilized steels exhibit higher strength at elevated temperature. For service in a corrosive environment in the sensitizing temperature range of 425 to 870 °C (800 to 1600 °F), an austenitic steel stabilized with niobium-plus-tantalum or titanium is needed. The filler metal used for welding should also be of a stabilized composition. Because an inert shielding gas is used, GTAW and GMAW are suitable for titanium-stabilized steel without oxidizing the titanium. Under certain conditions, stabilized stainless steel weldments are susceptible to sensitization, which occurs in narrow zones of the base metal immediately adjacent to the line of weld fusion. During welding, stabilized carbides are dissolved and, as a result of rapid cooling, are retained in solution.

Subsequent reheating to about 650 °C (1200 °F) results in preferential precipitation of chromium carbides in a narrow zone that exhibits less than normal corrosion resistance.

Microfissuring in Welded Joints. Interdendritic cracking in the weld area that occurs before the weld cools to room temperature is known as hot cracking or microfissuring. The occurrence of microfissuring is related to the:

- Microstructure of the weld metal as solidified
- Composition of the weld metal, especially the content of certain residual or trace elements
- Amounts of stress developed in the weld as it cools
- Ductility of the weld metal at high temperatures
- Presence of notches

Susceptibility to microfissuring is highly dependent on the microstructure of the weld metal. Weld metal with a wholly austenitic microstructure is considerably more susceptible to microfissuring than weld metal with a duplex structure of δ -ferrite in austenite. The content of alloying elements and residual elements strongly influences the susceptibility of fully austenitic stainless steel weld metal to microfissuring. Susceptibility can be reduced by a small increase in carbon or nitrogen content or by a substantial increase in manganese content. Residual or trace elements that contribute to microfissuring are boron, phosphorus, sulfur, selenium, silicon, niobium, and tantalum.

The amount of stress imposed on austenitic stainless weld metal as it cools from the solidus down to about 980 °C (1800 °F) should be minimized. In this temperature range, the weld metal is most susceptible to microfissuring, and if the level of stress is high, the fissures propagate to form visible cracks. Peening is not an effective method of preventing this type of cracking because it can seldom be applied early enough to reduce stress buildup.

Prevention of Microfissuring. To obtain duplex-structured weld metal that has a controlled ferrite content of at least 3 to 5 ferrite number (FN), a filler metal of suitable composition is selected. The ferrite number is a magnetically determined scale of ferrite measurement. The Welding Research Council Advisory Subcommittee on Welding Stainless Steels determined that the ferrite number of a weld metal, at least from 0 to 6 FN, approximates the average value of percent ferrite assigned by laboratories applying metallographic measurements of ferrite to a given weld metal.

Microfissuring can be prevented or minimized by the proper control of ferrite in the weld metal. Wide use has been made of the Schaeffler diagram (Fig. 42) to determine the approximate amount of ferrite that will be obtained in the austenitic weld metal of a given composition. Point X indicates the equivalent composition of a type 318 (316Cb) weld deposit containing 0.07C-1.55Mn-0.57Si-18.02Cr-11.87Ni-2.16Mo-0.80Nb. To determine the chromium and nickel equivalents, each percentage was multiplied by the potency factor indicated for the respective element along the axes of the diagram. When these were plotted as point X, the constitution of the weld was indicated as austenite plus 0 to 5% ferrite. Magnetic analysis of an actual sample revealed an average 2 FN. For austenite-plus-ferrite structures, the diagram predicts ferrite within 4% for stainless steel types 308, 309, 309Cb, 310, 312, 316, 317, and 318. Actual measurements of ferrite content can be made conveniently with the aid of a magnetic analysis device. American Welding Society (AWS) A4.2-74, "Standard Procedures for Calibrating Magnetic Instruments to Measure the Delta Ferrite Content of Austenitic Stainless Steel Weld Metal," and A5.4-81, "Specification for Covered Corrosion-Resisting Chromium and Chromium-Nickel Steel Welding Electrodes," discuss this measurement.

Fig. 42 Schaeffler diagram. See Fig. 30 for revised Schaeffler diagram.

Because many heats of austenitic stainless steel contain appreciable amounts of nitrogen (a very strong austenitizer), a revised constitution diagram for austenitic stainless steel weld metal has been developed to include nitrogen in the nickel equivalent (Fig. 30). Compared to Fig. 42, Fig. 30 is modified in shape and slope to improve the accuracy of ferrite estimation for types 309, 309Cb, 316, 316L, 317, 317L, and 318. In addition, ferrite calculation for types 308 and 347 weld metal is improved on samples with either high or low nitrogen content. For use in the diagram, actual nitrogen content is preferred. If it is not available, the following nitrogen value shall be used: 0.12% for self-shielding flux cored electrode GMAW welds, 0.08% for other GMAW welds, and 0.06% for welds of other processes.

When the weld metal must be wholly austenitic (that is, when the metal must be nonmagnetic or when specific corrosive environments that selectively attack δ -ferrite will be encountered), the content of crack-promoting residual elements must be stringently controlled, and the composition of the weld metal must be adjusted to increase crack resistance. Crack resistance can be increased by modifying the carbon, manganese, sulfur, phosphorus, silicon, and nitrogen contents of the weld metal. However, even with optimum compositions and the most favorable welding procedures, wholly austenitic weld deposits are more crack sensitive than those of a duplex structure.

Underbead cracking can occur in the heat-affected zones adjacent to welds in austenitic stainless steel, particularly when the weld zone is heavily restrained or the section thickness is greater than 19 mm ($\frac{3}{4}$ in.). Such cracking is most common in type 347 because of the strain-induced precipitation of niobium carbides, but it has been reported in other types as well. Weld restraint is the most important factor in the control of underbead cracking. Preheating is of little value in preventing cracking of austenitic stainless steel and can cause other problems, such as increased carbide precipitation.

Selection of Filler Metals. Electrodes and welding rods suitable for use as filler metal in the welding of austenitic stainless steels are shown in Table 35. These filler metals, with AWS standard composition specifications, are for GMAW, SAW, and SMAW. The selection of filler metals for welding austenitic stainless steels requires consideration of the microstructural constituents of the as-deposited weld metal. Ultimately, these microstructural constituents determine

the mechanical properties, crack sensitivity, and corrosion resistance of the weld. The constituents of principal concern are austenite, δ -ferrite, and precipitated carbides.

Table 35 Suggested filler metals for stainless steels

AISI No.	Recommended filler metal ^(a)		Remarks
	First choice	Second choice	
Chromium-nickel-manganese austenitic nonhardenable

(a) Use E, electrode, or R, welding rod, prefix.

Some filler metals, such as types 309Cb and 310, invariably deposit a fully austenitic weld metal. In these alloys, the ratio of ferrite formers to austenite formers cannot, within permissible limits, be raised high enough to produce any δ -ferrite in the austenite. Consequently, when these filler metals are applied to restrained joints or to base metals containing additions of elements such as phosphorus, sulfur, selenium, and silicon, only those procedures proved suitable by experience should be used.

The compositions of most filler metals are adjusted by the manufacturers to produce weld deposits that have ferrite-containing microstructures. Thus, ferrite-forming elements, such as chromium and molybdenum, are maintained at the high side of their allowable ranges, and austenite-forming elements, such as nickel, are kept low. The amount of ferrite in the structure of the weld metal depends on the ratio or balance of these elements. At least 3 or 4 FN δ -ferrite is needed in the as-deposited weld metal for effective suppression of hot cracking. With the proper techniques, however, types 316 and 316L can be welded with as little as 0.5 FN. Ferrite-containing weld metal may have certain disadvantages in a welded austenitic stainless steel. Ferrite is ferromagnetic, and the increased magnetic permeability of the weld metal may be objectionable in applications that require nonmagnetic properties. When exposed to service at elevated temperature, the ferrite in some weld metals may transform to σ phase and adversely affect mechanical properties and corrosion resistance, a problem that has been encountered in power plant applications.

When a joint is arc welded without the addition of filler metal, the structure of the weld metal is determined by the composition of the base metal. Sometimes this leads to unfavorable results, because wrought base metals may not have the compositional limits required for good weld metal.

Preheating. In general, no benefit is derived from preheating austenitic stainless steels. In some applications, preheating can increase carbide precipitation, cause shape distortion of the workpiece, or increase hot-cracking tendencies.

Postweld Stress Relieving. Although the effects of residual stress from welding on the properties of austenitic stainless steels are limited in comparison to the effects of cold working, residual stress may significantly affect the mechanical properties. Because the effective yield strength varies from point to point, the application of further stresses at later stages of fabrication can cause excessive distortion and even premature failure. Nonuniform heating, which relieves some local residual stress, may also contribute to distortion. For these reasons, stress relieving may be required to ensure dimensional stability.

Stress relieving can be performed over a wide range of temperatures, depending on the amount of relaxation required. Time at temperature ranges from about 1 h per inch of section thickness at temperatures above 650 °C (1200 °F) to 4 h per inch of section thickness at temperatures below 650 °C (1200 °F). Because of the high coefficient of expansion and the low thermal conductivity of austenitic stainless steels, cooling from the stress-relieving temperature must be slow. The stress-relieving temperature selected must be compatible with the extent of carbide precipitation acceptable and with the corrosion resistance desired. Nonstabilized stainless steels cannot be stress relieved in the sensitizing temperature range without sacrifice of corrosion resistance. Extralow-carbon stainless steels are affected much less, because carbide precipitation in these steels is sluggish. Stabilized stainless steels exhibit minimal chromium carbide precipitation tendencies.

For austenitic stainless steels, the estimated percentages of residual stress relieved at various temperatures, for the times previously noted, are:

Temperature		Stress relief, %
°C	°F	
845-900	1550-1650	85

Ferritic Stainless Steels. The ferritic stainless steels are generally less weldable than the austenitic stainless steels and produce welded joints having lower toughness because of grain coarsening that occurs at the high welding temperatures. The standard ferritic stainless steels are:

- Type 446 (25% Cr)
- Types 430, 430F, and 430F-Se (17% Cr)
- Types 405 and 409 (13% Cr)

Type 409 is ferritic because it has a low carbon content (0.08% max) and a minimum titanium content equal to six times the carbon content. Type 405, which also contains only 0.08% C (max), contains an average of 0.20% Al, which promotes ferrite formation.

There are a number of ferritic stainless steels that contain very low amounts of carbon and nitrogen. The low-interstitial ferritic stainless steels (including the 26Cr-1Mo and 29Cr-4Mo alloys) can be welded so that they do not lose any of the base metal ductility in the weld area, while retaining grain growth. The key to the successful welding of these steels is to prevent any carbon, nitrogen, or oxygen contamination during welding. Thus, the part and filler material must be clean before welding, and both the molten weld metal and the hot weld-area metal must be fully shielded from the atmosphere. All moisture must be excluded from the weld area before and during welding.

Effect of Welding Heat on Ductility and Grain Size. Although most ferritic stainless steels have compositions that ensure a ductile ferritic structure at room temperature, variations in composition within the standard compositional limits can result in the formation of small amounts of austenite during heating to elevated temperature. Upon cooling, the austenite transforms to martensite, resulting in a duplex structure of ferrite and a small amount of martensite. The martensite reduces both the ductility and toughness of the steel. Annealing transforms the martensite and restores normal ferritic properties, but annealing increases costs and can result in an excessive amount of distortion, particularly in parts that were previously formed by a cold-working process.

All ferritic stainless steel mill products are normally annealed at the mill to transform any martensite that may be present to a softer structure of ferrite and carbides. In this condition, the steel can be readily cold formed. Only when the steel is heated near or above the transformation temperature (approximately 870 °C, or 1600 °F), as during welding, does the risk of austenite formation and subsequent transformation to martensite arise. In addition, heating to temperatures above 955 °C (1750 °F) results in enlargement of the ferrite grain size, which also reduces the ductility and toughness of the steel. Although martensite can be eliminated by annealing, coarsened ferrite grains remain unaffected. Because martensite responds to annealing and inhibits ferrite grain growth, some applications may benefit from martensite formation, provided that the workpiece can be annealed after welding. In a 17% Cr steel, martensite formation is promoted by lowering the chromium content to 15 to 16%. When this practice is adopted, it is usually necessary to preheat before welding or to select a steel of lower carbon content to guard against cracking in the HAZ.

When postweld annealing is not feasible, the ductility of the welded joint can be controlled by the selection of a stainless steel base metal containing substantial amount of strong ferrite-former, such as aluminum, niobium, or titanium. One such steel, which has the commercial designation of type 430Ti, is a 17% Cr steel containing 0.12% C (max) and a minimum titanium content equal to six times the carbon content. The metallurgical functions of the titanium in this steel are to form stable titanium carbides and to promote the formation of ferrite. When a completely ferritic steel is welded, no martensite is formed in the HAZ, although some grain coarsening may occur. Grain coarsening can be controlled, to some extent, by minimizing heat input during welding and by avoiding slow cooling from the weld temperature.

Effect of Temperature on Notch Toughness. For the 17% Cr steels, the temperature range is just above room temperature for transition from a tough shear-type fracture at the higher temperature to a brittle, cleavage-type fracture at the lower temperature, upon impact at a notch. Under impact loading at room temperature and below, these steels are notch sensitive, and impact test values of less than 20 J (15 ft · lbf) are usual. At 95 to 120 °C (200 to 250 °F), the impact test values increase to approximately 40 to 70 J (30 to 50 ft · lbf).

This relationship between notch toughness and temperature is important in the selection of joint design and welding conditions for ferritic stainless steel. In service, a weldment designed primarily to withstand static load may be subjected to accidental or unforeseen impact loading. Furthermore, a weldment with low notch toughness may not withstand an appreciable number of cyclical stresses even under a low rate of loading. Because multiaxial residual stresses are often developed during welding (especially when welding heavy sections), notches and points of stress concentration that might cause failure in service must be avoided whenever possible. Preheating before welding is often useful in preventing cracking during welding.

Preheating. The recommended preheating temperature range for ferritic stainless steels is 150 to 230 °C (300 to 450 °F). The need for preheating is determined largely by the composition, mechanical properties, and thickness of the steel being welded. Steels less than 6.4 mm ($\frac{1}{4}$ in.) thick are much less likely to crack during welding than those of greater thickness. The type of joint, joint location, restraints imposed by clamping and jiggling, welding process, and rate of cooling from the welding temperature can also affect weld cracking.

Postweld Annealing. The temperature range for postheating or postweld annealing of ferritic stainless steels is 790 to 845 °C (1450 to 1550 °F), which is safely below the temperatures for austenitic formation and grain coarsening. Annealing transforms a mixed structure to a wholly ferritic structure and restores the mechanical properties and corrosion resistance that may have been adversely encountered in welding. Thus, except for its inability to refine coarsened ferrite grains, annealing is generally beneficial. Annealing has two major disadvantages: the time and cost of the treatment, and the need to prevent the formation of the oxide scale or to remove it if it is already present. Annealing may also require the use of elaborate fixturing to prevent sagging or distortion of the weldment.

Cooling ferritic stainless steel from the annealing temperature may be done by air or water quenching. To minimize distortion from handling, weldments are often allowed to cool to about 595 °C (1100 °F) before they are removed from the furnace. Slow cooling through the temperature range of 565 to 400 °C (1050 to 750 °F) must be avoided because it produces brittleness in the steel. Susceptibility to this type of embrittlement, known as 475 °C (885 °F) embrittlement, normally increases as chromium content increases. Heavy sections may require forced cooling or a spray quench to bring them safely through this embrittlement range.

Selection of Filler Metal. As shown in Table 35, both ferritic and austenitic stainless steel filler metals are used in the arc welding of ferritic stainless steel. Ferritic stainless steel filler metals offer the advantages of having the same color and appearance, the same coefficient of thermal expansion, and essentially the same corrosion resistance as the base metal. However, austenitic stainless steel filler metal are often used to obtain more ductile weld metal in the as-welded condition.

Although austenitic stainless steel weld metal does not prevent grain growth or martensite formation in the HAZ, the ductility of austenitic weld metal improves the ductility of the welded joint. The selection of austenitic stainless steel filler metal, however, should be carefully related to the specific application to determine whether differences in color or in the physical corrosion and mechanical properties of the weld metal and the base metal cause difficulty.

For weldments that are to be annealed after welding, the use of austenitic filler metal can introduce several problems. The normal range of annealing temperature for ferritic stainless steels falls within the sensitizing temperature range for austenitic steels. Consequently, unless the austenitic weld metal is of extralow-carbon content or is stabilized with

niobium or titanium, its corrosion resistance may be seriously impaired. If the annealing treatment is intended to relieve residual stress in the weldment, it cannot be fully effective because of the difference in the coefficients of thermal expansion of the weld metal and the base metal.

Corrosion Resistance. Ferritic stainless steels usually exhibit less corrosion resistance than austenitic stainless steels. Any condition of the welded joint that might therefore impair corrosion resistance must be avoided. The presence of martensite or the precipitation of σ phase at the grain boundaries can cause severe intergranular corrosion in the HAZ. Completely ferritic steels, such as types 430Ti and 446, display little or no susceptibility to intergranular attack at the weld joint. Annealing of any welded ferritic steel eliminates the unfavorable structural conditions that promote corrosive attack.

Martensitic Stainless Steels. The standard martensitic stainless steels are types 403, 410, 414, 416, 416Se, 420, 431, 440A, 440B, and 440C. These steels derive their corrosion resistance from chromium, which they contain in proportions ranging from 11.5 to 18%. Martensitic stainless steels are the most difficult stainless steels to weld because they are chemically balanced to become harder, stronger, and less ductile through thermal treatment. These same metallurgical changes occur from the heat of welding. As a result of welding, these changes are restricted to the weld area and are not uniform over the entire section. The nonuniform metallurgical condition of the part makes it susceptible to cracking when subjected to the high stresses from welding. Increasing carbon content in martensitic stainless steels generally results in increased hardness and reduced ductility. Thus, the three type 440 stainless steels are seldom considered for applications that require welding, and filler metals of the type 440 compositions are not readily available.

Modifications of the standard martensitic steels contain additions of elements such as nickel, molybdenum, vanadium, and tungsten, primarily to raise the allowable service temperature above the 595 °C (1100 °F) limit for the standard steels. When these elements are added, carbon content is increased, and the problem of avoiding cracking in the hardened HAZ of weldments becomes more serious.

Martensitic stainless steels can be welded in the annealed, hardened, and hardened and tempered conditions. Regardless of the prior condition of the steel, welding produces a hardened martensitic zone adjacent to the weld. The hardness of the HAZ depends primarily on the carbon content of the base metal. As hardness increases, toughness decreases, and the zone becomes more susceptible to cracking. Preheating and control of the interpass temperature are the most effective means of avoiding cracking. Postweld heat treatment is required to obtain optimum properties.

Preheating and Postweld Heat Treating. The usual preheating temperature range of martensitic steels is 205 to 315 °C (400 to 600 °F). The carbon content of the steel is the most important factor in determining whether preheating is necessary. On the basis of carbon content alone, a steel containing not more than 0.10% C seldom requires preheating, and one with more than 0.10% C requires preheating to prevent cracking. Other factors that determine the need for preheating are the mass of the joint, degree of restraint, presence of a notch effect, and composition of the filler metal. Correlations of preheating and postweld heat-treating practice with carbon contents and welding characteristics of martensitic stainless steels can be used:

- Carbon below 0.10%: Neither preheating nor postweld annealing is generally required; steels which carbon contents this low are not standard
- Carbon 0.10 to 0.20%: Preheat to 260 °C (500 °F); weld at this temperature; cool slowly
- Carbon over 0.20 to 0.50%: Preheat to 260 °C (500 °F); weld at this temperature; anneal
- Carbon over 0.50%: Preheat to 260 °C (500 °F); weld with high heat input; anneal

If the weldment is to be hardened and tempered immediately after welding, annealing may be omitted. Otherwise, the weldment should be annealed immediately after welding, without cooling to room temperature.

The functions of a postweld heat treatment are:

- To temper or anneal the weld metal and HAZ to optimize hardness, toughness, and strength for the intended application
- To decrease residual stresses associated with welding

Postweld heat treatments normally used for martensitic stainless steels are subcritical annealing and full annealing (Ref 89).

The necessity for a postweld heat treatment depends on the composition of the steel, the filler metal, and the service requirements. Full annealing transforms a multiple-phase weld zone to a wholly ferritic structure. This annealing procedure requires proper control of the complete thermal cycle. It should not be used unless maximum softness is required because of the formation of coarse carbides in the microstructure that take longer to dissolve at the austenitizing temperature. Typical postweld annealing temperatures are given in Table 36.

Table 36 Annealing treatments for martensitic stainless steels

Type	Subcritical annealing temperature range, °C (°F)^(a)	Full annealing temperature range, °C (°F)^(b)
403, 410, 416	650-760 (1200-1400)	830-885 (1525-1625)
414	650-730 (1200-1350)	Not recommended
420	675-760 (1250-1400)	830-885 (1525-1625)
431	620-705 (1150-1300)	Not recommended
440A, 440B, 440C	675-760 (1250-1400)	845-900 (1550-1650)
CA-6NM	595-620 (1100-1150)	790-815 (1450-1500)
CA-15, CA-40	620-650 (1150-1200)	845-900 (1550-1650)

Source: Ref 89

(a) Air cool from temperature; lowest hardness is obtained by heating near the top of the range.

(b) Furnace cool to 595 °C (1100 °F); weldment can then be air-cooled.

Precipitation-Hardening Stainless Steels. Steels are divided into three groups on the dual basis of characteristic alloying additions, particularly the elements added to promote precipitation hardening, and the matrix structures of the steels in the solution-annealed and aged condition. Because differences among the steels have a direct bearing on the behavior of the steels in heat treatment and welding, the metallurgical characteristics of each are considered separately.

Martensitic Precipitation-Hardening Steels. These steels have a predominantly austenitic structure at the solution-annealing temperature of approximately 1040 to 1065 °C (1900 to 1950 °F), but they undergo an austenite-to-

martensite transformation when cooled to room temperature. The temperature at which martensite starts to form from austenite upon cooling, M_s , is usually in the range of 95 to 150 °C (200 to 300 °F). When martensite is reheated to 480 to 595 °C (900 to 1100 °F), precipitation hardening and strengthening occur, promoted by the presence of one or more alloying additions. Molybdenum, copper, titanium, niobium, and aluminum (and their compounds) are dissolved during annealing and retained in solid solution by rapid cooling, producing precipitate (usually submicroscopic particles) that increases both the strength and the hardness of the martensitic matrix.

The compositional balance in the martensitic precipitation-hardening (PH) steels is critical, because relatively slight variations can lead to the formation of excessive amounts of δ -ferrite during solution annealing. If the austenite is too stable, large amounts of austenite can also be retained at room temperature after solution annealing. Either of these two conditions prevents full hardening during aging. Carbon and nitrogen contents can significantly affect this balance. Increased carbon or nitrogen may result in contamination. Typical sources of these contaminants are shop dirt and the atmosphere.

These steels can be readily welded. The welding procedures resemble those ordinarily used for the 300-series stainless steels, despite differences in composition and structure between the two classes. The formation of martensite, which occurs during cooling from elevated temperatures, as in welding, does not result in full hardening. These steels are not sensitive to cracking and do not require preheating.

The selection of filler metal depends on the properties required for the welded joint (Table 37). If strength comparable to that of the base metal is not required at the welded joint, a tough 300-series stainless steel filler metal may be adequate. When a weld having mechanical properties comparable to those of the hardened base metal is desired, the filler metal must be of comparable composition, although slight modifications are permissible to obtain better weldability.

Table 37 Recommended filler metals for welding precipitation-hardening stainless steels

Type	UNS designation	Covered electrodes	Bare welding wire	Dissimilar PH stainless steels
Martensitic				
17-4 PH	S 17400	AMS 5827B (17-4 PH) or E308	AMS 5826 (17-4 PH) or ER308	E309 or ER309, E309Cb or ER309Cb
15-5 PH	S 15500	AMS 5827B (17-4 PH) or E308	AMS 5826 (17-4) or ER308	E309 or ER309, E309Cb or ER309Cb
Semiaustenitic				
17-7 PH	S 17700	AMS 5827B (17-4 PH), E308, or E309	AMS 5824A (17-7 PH)	E310 or ER 310, ENiCrFe-2, or ERNiCr-3
PH 15-7 Mo	S 15700	E308 or E309	AMS 5812C (PH 15-7 Mo)	E309 or ER309, E310 or ER310
AM350	S 35000	AMS 5775A (AM350)	AMS 5774B (AM 350)	E308 or ER308, E309 or ER309
AM355	S 35500	AMS 5781A (AM355)	AMS 5780A (AM 355)	E308 or ER308, E309 or ER309

When welds are deposited in a single pass, the weld metal and the HAZ usually respond uniformly to a postweld precipitation-hardening heat treatment. There is seldom any significant variation in hardness across the joint. Multiple-pass weld, however, exhibit less uniform response to the same heat treatment because successive applications of heat during welding result in marked variations in the structure of weld metal, HAZ, and base metal. Annealing eliminates these variations and provides a more uniform microstructure capable of responding uniformly to precipitation hardening.

Semiaustenitic Precipitation-Hardening Steels. Unlike martensitic PH steels, semi-austenitic PH steels are soft enough in the annealed condition to permit cold working. When cooled rapidly from the annealing temperature to room temperature, they retain their austenitic structure, which displays good toughness and ductility in cold-forming operations. The M_s temperatures for these steels are well below room temperature, but they vary depending on composition and annealing temperature.

To obtain hardening and strengthening, the austenitic structure must be transformed to an essentially martensitic one. This can be accomplished by treating the steel before subjecting it to the precipitation-hardening heat treatment by:

- Heating the steel in the range of 650 to 870 °C (1200 to 1600 °F) to precipitate carbides and other compounds, thereby depleting the matrix of enough austenite-stabilizing elements to allow transformation of austenite to martensite when the steel is cooled to room temperature
- Refrigerating the steel to a temperature well below the M_s point (-75 °C, or -100 °F, for example)
- Cold working the steel enough so that the austenite transforms to martensite

After transformation to martensite, the semiaustenitic PH steels, like the martensitic PH steels, respond to precipitation hardening in the temperature range of 455 to 595 °C (850 to 1100 °F). Whether a precipitate forms or a tempering reaction takes place depends on the steel composition.

The M_s temperature of the semiaustenitic PH steels is controlled by the solution-annealing temperature, as well as by composition. For example, when AM-350 steel is solution annealed at temperatures below 925 °C (1700 °F), incomplete carbide solution raises the M_s temperature above room temperature. On the other hand, when the solution-annealing temperature is raised above 925 °C (1700 °F), the M_s temperature drops precipitously. In practice, the solution-annealing temperature is not permitted to exceed about 1050 °C (1925 °F), because higher temperatures promote the formation of δ -ferrite.

The semiaustenitic PH steels are normally welded in the annealed condition. The tough austenitic structure imparts welding characteristics similar to those of 300-series stainless steels. The semiaustenitic PH steels are not susceptible to cracking when welded, even when welded after transformation to martensite, because the low-carbon martensite developed is not of high hardness or low ductility. Also, cold cracking does not occur in the base metal adjacent to the weld because the HAZ is austenitized during welding and remains substantially austenitic as the joint cools to room temperature.

The choice of filler metal depends largely on the weld properties desired. The filler metal can be an alloy of precipitation-hardening composition capable of developing mechanical properties comparable to those of the base metal (Table 37). If high strength is not requisite, the filler metal can be a 300-series austenitic stainless steel. When these steels are welded in the annealed condition, certain microstructural relations are generally obtained as a result of relatively rapid heating and cooling at the joint:

- Weld metal contains small amounts of ferrite in an essentially austenitic matrix; hardness is approximately 90 HRB
- Base metal immediately adjacent to the weld displays high-temperature annealed (austenitic) structure;

hardness is approximately 90 HRB

- Base metal in the narrow zone just beyond the annealed zone next to the weld is hardened slightly; hardness is approximately 90 to 98 HRB

If the welded assembly is given the customary double-aging heat treatment, the three areas identified above, as well as the unaffected base metal, transform and precipitation harden uniformly to a hardness range commensurate with the precipitation-hardening temperature. The weld metal may be somewhat less tough than the wrought base metal, as measured by the results of tensile-elongation and bend tests, depending on the type of joint, the welding process, and the hardening temperature.

Higher precipitation-hardening temperature ensure good weld toughness with little sacrifice of strength. Maximum toughness requires the annealing of the weldment prior to the transformation and hardening treatments. Although other variations in the welding and heat-treating sequence are possible and may be desirable at times, the choice of the sequence should ensure that, after welding, the weld metal and the HAZ are in the annealed (austenitic) condition. To harden these areas, both the transformation and the precipitation-hardening heat treatments must be applied. If the components are given the transformation treatment before welding, the precipitation-hardening treatment alone, after welding, produces no significant hardening in either the weld metal or the HAZ.

Austenitic Precipitation-Hardening Steels. The alloy content of these steels is high enough to maintain an austenitic structure after annealing and after any aging or hardening treatment. The precipitation-hardening phase is soluble at the annealing temperature of 1095 to 1120 °C (2000 to 2050 °F), and it remains in solution during rapid cooling from the annealing temperature. When these steels are reheated to about 650 to 760 °C (1200 to 1400 °F), precipitation occurs, and the hardness and strength of the austenitic structure increase. The hardness attained is lower than that of the martensitic or semiaustenitic PH steels, but the non-magnetic properties are retained. Although the austenitic PH steels remain austenitic during all phases of forming, welding, and heat treatment, some contain alloying elements (for precipitation-hardening purposes) that greatly affect behavior in welding.

The austenitic precipitation-hardening stainless steels can be welded using the arc welding techniques described earlier in the section "Weldability" for the austenitic stainless steels. The major difference is that these steels are usually heat treated after welding to achieve the required mechanical properties, which is usually unnecessary with austenitic PH stainless steels. Austenitic precipitation-hardening stainless steels may be welded with matched or dissimilar filler metals or without filler metals, as is the case with most stainless steels. There is a wide variety of hardenable filler metals available for these PH grades through the manufacturer of consumables. The most commonly used grade is the 630 alloy, the only one currently included in the AWS specifications. Its composition is shown in Table 38.

Table 38 Chemical compositions of welding consumables for precipitation-hardening stainless steels

All are maximum percentages.

AWS classification	Composition, %									
	C	Cr	Ni	Mo	Nb + Ta	Mn	Si	P	S	Cu
E630 ^(a) , ER630 ^(b)	0.05	16.0-16.75	4.5-5.0	0.75	0.15-0.30	0.25-0.75	0.75	0.04	0.03	3.25-4.00

(a) Undiluted weld metal composition.

(b) Consumable composition.

Duplex Stainless Steels (Ref 90, 91, 92). The physical and mechanical properties of duplex stainless steels affect the welding process. Because of their better stress-corrosion cracking resistance and appreciably higher yield and tensile strengths, these steels are currently used as direct substitutes for austenitic stainless steels when service above about 260 to 315 °C (500 to 600 °F) is not required.

Duplex stainless steels are magnetic and have yield strengths typically about double that of type 316L, with tensile strengths considerably higher than those of standard austenitic grades. Duplex stainless steels also generally have a higher thermal conductivity and a lower coefficient of thermal expansion than austenitic stainless steels. Because of these factors, duplex stainless steels generally exhibit less distortion during welding than do austenite stainless steels.

The general welding characteristics of the duplex alloy steels are very similar to those of austenitic stainless steels. They can be welded by any of the conventional arc welding processes. The normal arc welding processes, shielded metal arc, gas tungsten arc, gas metal arc, plasma arc, and submerged arc welded can all be used. In addition, electron beam and laser welding are used, as well as resistance welding. Heat input should be low enough to minimize intergranular carbide precipitation. Surface cleanliness is a must when welding duplex stainless steels. It is necessary to eliminate any source of hydrogen in the welding operation. For the gas-shielded processes, particularly on pipe, argon-helium purge gas should be used.

Two differences between the characteristics of duplex stainless steels and those of austenitic stainless steels can be discerned:

- Because duplex materials are appreciably stiffer than austenitic grades, greater forces are required for tube rolling into tube sheets, and so on
- Because duplex alloys are highly sensitive to 475 °C (885 °F) and σ phase embrittlement control over interpass temperature is imperative

It is good practice to weld austenitic grades at a maximum interpass temperature of approximately 200 °C (390 °F), but, in cases such as multipass orbital GTAW of pipe, interpass temperatures well above this level can often be tolerated with no significant adverse effect. These situations should be regarded with caution for duplex alloys, in view of embrittlement following prolonged exposure to temperatures much above 300 °C (570 °F), and a maximum interpass temperature of 200 °C (390 °F) is suggested.

Wrought duplex stainless steels typically contain elongated islands of austenite in a ferrite matrix, as seen in Fig. 43. Generally, weld metal contain less austenite than parent metal of the same composition. As-welded properties may be reduced because of this change in structure. Welding parameters and/or consumables are chosen to optimize the mechanical properties and corrosion resistance of the weld. Useful properties have been obtained using duplex stainless consumables with increased nickel to maintain sufficient austenite in the weld (Fig. 44). Slightly slower cooling rates after welding also permit more time for austenite formation and can improve as-welded mechanical properties and corrosion resistance. Weldments may also be annealed to optimize properties, but this is not always practical. It is essential that thorough cleaning be done after welding.

Fig. 43 Photomicrograph of a duplex stainless steel showing elongated austenite islands in the ferrite matrix. The mill-annealed 19.1 mm (0.752 in.) thick plate sample is a longitudinal section etched using 15 ml HCl in

Fig. 44 Photomicrograph of a duplex stainless weld obtained using consumables with increased nickel to retain sufficient austenite in the weld. Typical weld metal microstructure for gas metal arc weld in 19.1 mm (0.752 in.) thick plate. The light-etching phase is austenite. The micrograph shows a cross section etched in Groesbeck's reagent. 200×

Test weldments may be evaluated in the laboratory before vessel fabrication and service exposure. The welding techniques, filler metal, and plate thickness studied in these evaluations are typically the same as those employed in field fabrication. Corrosion evaluation of weldments should employ environments and stress levels based on service expectations.

Filler metal selection is critical. A filler metal with matching composition may result in a higher ferrite content than that of the base metal. Gooch (Ref 91) and others have shown that filler metals of duplex stainless steel with higher nickel and/or nitrogen are preferred. Weld metal cracking in duplex steels has rarely been identified. Because extensive austenite-to-ferrite and ferrite-to-austenite transformations occur in the HAZ, along with grain growth, the welding procedure must be carefully controlled. The extent of the above transformations depends to a great extent on the composition and the precise weld thermal cycle experienced by the HAZ during welding. Because of their high chromium level, these steels are prone to σ phase and 475 °C (885 °F) embrittlement. Though the weld thermal cycle is too short for σ -phase formation of 475 °C (885 °F) embrittlement to occur, care must be exercised in welding heavy-section steels of this type.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Introduction

STAINLESS STEELS are a class of chromium-containing steels widely used for their corrosion resistance in aqueous environments and for service at elevated temperatures. Stainless steels are distinguished from other steels by the enhanced corrosion and oxidation resistance created by chromium additions. Chromium imparts passivity to ferrous alloys when present in amounts of more than about 11%, particularly if conditions are strongly oxidizing. Consequently, steels with more than 10 or 12% Cr are sometimes defined as stainless steels.

This article reviews the properties of cast steels that are specified either for liquid corrosion service at temperatures below 650 °C (1200 °F) or for service at temperatures above 650 °C (1200 °F). The cast steels suitable for these applications are often high-alloy compositions because carbon and low-alloy steels do not provide sufficient corrosion resistance and/or strength at elevated temperatures. These high-alloy cast steels generally have more than 10% Cr and primarily consist of stainless steel compositions.

Stainless steel castings are usually classified as either corrosion-resistant castings (which are used in aqueous environments below 650 °C, or 1200 °F) or heat-resistant castings (which are suitable for service temperatures above 650 °C, or 1200 °F). However, this line of demarcation in terms of application is not always distinct, particularly for steel castings used in the range from 480 to 650 °C (900 to 1200 °F). The usual distinction between heat-resistant and corrosion-resistant cast steels is based on carbon content.

In general, the cast and wrought stainless steels possess equivalent resistance to corrosive media and they are frequently used in conjunction with each other. Important differences do exist, however, between some cast stainless steels and their wrought counterparts. One significant difference is in the microstructure of cast austenitic stainless steels. There is usually a small amount of ferrite present in austenitic stainless steel castings, in contrast to the single-phase austenitic structure of the wrought alloys. The presence of ferrite in the castings is desirable for facilitating weld repair, but ferrite also increases resistance to stress-corrosion cracking. There have been only a few stress-corrosion cracking failures with cast stainless steels in comparison to the approximately equivalent wrought compositions. The principal reasons for this resistance are apparently:

- Silicon added for fluidity gives added benefit from the standpoint of stress-corrosion cracking
- Sand castings are usually tumbled or sandblasted to remove molding sand and scale; this probably tends to put the surface in compression

Wrought and cast stainless steels may also differ in mechanical properties, magnetic properties, and chemical content. Because of the possible existence of large dendritic grains, intergranular phases, and alloy segregation, typical mechanical properties of cast stainless steels may vary more and generally are inferior to those of any wrought structure.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Grade Designations and Compositions

Cast stainless steels are most often specified on the basis of composition using the designation system of the High Alloy Product Group of the Steel Founders' Society of America. (The High Alloy Product Group has replaced the Alloy Casting Institute, or ACI, which formerly administered these designations.) The first letter of the designation indicates whether the alloy is intended primarily for liquid corrosion service (C) or high-temperature service (H). The second letter denotes the nominal chromium-nickel type of the alloy (Fig. 1). As nickel content increases, the second letter of the designation is

changed from A to Z. The numeral or numerals following the first two letters indicate maximum carbon content (percentage $\times 100$) of the alloy. Finally, if further alloying elements are present, these are indicated by the addition of one or more letters as a suffix. Thus, the designation of CF-8M refers to an alloy for corrosion-resistant service (C) of the 19Cr-9Ni type (Fig. 1), with a maximum carbon content of 0.08% and containing molybdenum (M).

Fig. 1 Chromium and nickel contents in ACI standard grades of heat- and corrosion-resistant steel castings. See text for details.

Some of the high-alloy cast steels exhibit many of the same properties of cast carbon and low-alloy steels (see the article "Steel Castings" in this Volume). Some of the mechanical properties of these grades (for example, hardness and tensile strength) can be altered by a suitable heat treatment. The cast high-alloy grades that contain more than 20 to 30% Cr plus Ni, however, do not show the phase changes observed in plain carbon and low-alloy steels during heating or cooling between room temperature and the melting point. These materials are therefore nonhardenable, and their properties depend on composition rather than heat treatment. Therefore, special consideration must be given to each grade of high-alloy cast steel with regard to casting design, foundry practice, and subsequent thermal processing (if any).

Compositions of C-Type (Corrosion-Resistant) Steel Castings. The C-type steel castings for liquid corrosion service are often classified on the basis of composition, although it should be recognized that classification by composition often involves microstructural distinctions (see the section "Composition and Microstructure" in this article). Table 1 lists the compositions of the commercial cast corrosion-resistant alloys. Alloys are grouped as:

- Chromium steels
- Chromium-nickel steels, in which chromium is the predominant alloying element
- Nickel-chromium steels, in which nickel is the predominant alloying element

The serviceability of cast corrosion-resistant steels depends greatly on the absence of carbon, and especially precipitated carbides, in the alloy microstructure. Therefore, cast corrosion-resistant alloys are generally low in carbon (usually lower than 0.20% and sometimes lower than 0.03%).

Table 1 Compositions and typical microstructures of ACI corrosion-resistant cast steels

ACI type	Wrought alloy type ^(a)	ASTM specifications	Most common end-use microstructure	Composition, % ^(b)

- (a) Type numbers of wrought alloys are listed only for nominal identification of corresponding wrought and cast grades. Composition ranges of cast alloys are not the same as for corresponding wrought alloys; cast alloy designations should be used for castings only.
- (b) Maximum unless a range is given. The balance of all compositions is iron.
- (c) Sulfur content is 0.04% in all grades except: CG-6MMN, 0.030% S (max); CF-10SMnN, 0.03% S (max); CT-15C, 0.03% S (max); CK-3MCuN, 0.010% S (max); CN-3M, 0.030% S (max); CA-6N, 0.020% S (max); CA-28MWV, 0.030% S (max); CA-40F, 0.20-0.40% S; CB-7Cu-1 and -2, 0.03% S (max). Phosphorus content is 0.04% (max) in all grades except: CF-16F, 0.17% P (max); CF-10SMnN, 0.060% P (max); CT-15C, 0.030% P (max); CK-3MCuN, 0.045% P (max); CN-3M, 0.030% P (max); CA-6N, 0.020% P (max); CA-28MWV, 0.030% P (max); CB-7Cu-1 and -2, 0.035% P (max).
- (d) Molybdenum not intentionally added.
- (e) CF-3A, CF-3MA, and CF-8A have the same composition ranges as CF-3, CF-3M, and CF-8, respectively, but have balanced compositions so that ferrite contents are at levels that permit higher mechanical property specifications than those for related grades. They are covered by ASTM A 351.
- (f) Nb, $8 \times \%C$ min (1.0% max); or Nb + Ta $\times \%C$ (1.1% max).
- (g) For CN-7MS, silicon ranges from 2.50 to 3.50%.

All cast corrosion-resistant steels contain more than 11% chromium, and most contain from 1 to 30% nickel (a few have less than 1% Ni). About two-thirds of the corrosion-resistant steel castings produced in the United States are of grades that contain 18 to 22% Cr and 8 to 12% Ni.

In general, the addition of nickel to iron-chromium alloys improves ductility and impact strength. An increase in nickel content increases resistance to corrosion by neutral chloride solutions and weakly oxidizing acids.

The addition of molybdenum increases resistance to pitting attack by chloride solutions. It also extends the range of passivity in solutions of low oxidizing characteristics.

The addition of copper to duplex (ferrite is austenite) nickel-chromium alloys produces alloys that can be precipitation hardened to higher strength and hardness. The addition of copper to single-phase austenitic alloys greatly improves their resistance to corrosion by sulfuric acid. In all iron-chromium-nickel stainless alloys, resistance to corrosion by environments that cause intergranular attack can be improved by lowering the carbon content. Information on the corrosion characteristics and mechanical properties of the C-type steel castings is provided in the section "Corrosion-Resistant Steel Castings" in this article.

Compositions of H-Type (Heat-Resistant) Steel Castings. Castings are classified as heat resistant if they are capable of sustained operation while exposed, either continuously or intermittently, to operating temperatures that result in metal temperatures in excess of 650 °C (1200 °F). Heat-resistant steel castings resemble high-alloy corrosion-resistant steels except for their higher carbon content, which imparts greater strength at elevated temperature. The higher carbon content and, to a lesser extent, alloy composition ranges distinguish cast heat-resistant steel grades from their wrought counterparts. Table 2 summarizes the compositions of standard cast heat-resistant grades and three grade variations (HK30, HK40, HT30) specified in ASTM A 351 for elevated-temperature and corrosive service of pressure-containing parts.

Table 2 Compositions of ACI heat-resistant casting alloys

ACI designation	UNS number	ASTM specifications ^(a)	Composition, % ^(b)

(a) ASTM designations are the same as ACI designations.

(b) Rem Fe in all compositions. Manganese content: 0.35 to 0.65% for HA, 1% for HC, 1.5% for HD, and 2% for the other alloys. Phosphorus and sulfur contents: 0.04% (max) for all but HP-50WZ. Molybdenum is intentionally added only to HA, which has 0.90 to 1.20% Mo; maximum for other alloys is set at 0.5% Mo. HH also contains 0.2% N (max).

(c) Also contains 4 to 6% W, 0.1 to 1.0% Zr, and 0.035% S (max) and P (max)

The three principal categories of H-type cast steels, based on composition, are:

- Iron-chromium alloys
- Iron-chromium-nickel alloys
- Iron-nickel-chromium alloys

Information on the properties of H-type grades of steel castings is contained in the section "Heat-Resistant Cast Steels" in this article.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Composition and Microstructure

As shown in Table 1, cast stainless steels can also be classified on the basis of microstructure. Structures may be austenitic, ferritic, martensitic, or ferritic-austenitic (duplex).

The structure of a particular grade is primarily determined by composition. Chromium, molybdenum, and silicon promote the formation of ferrite (magnetic), while carbon, nickel, nitrogen, and manganese favor the formation of austenite (nonmagnetic). For example, a cast extra-low-carbon grade such as 0.03% C (max) cannot be completely nonmagnetic unless it contains 12 to 15% Ni. The wrought grades of these alloys normally contain about 13% Ni. They are made fully austenitic to improve rolling and forging characteristics.

Chromium (a ferrite and martensite promoter), nickel, and carbon (austenite promoters) are particularly important in determining microstructure (see the section "Ferrite Control " in this article). In general, straight chromium grades of high-alloy cast steel are either martensitic or ferritic, the chromium-nickel grades are either duplex or austenitic, and the nickel-chromium steels are fully austenitic.

Ferrite in Cast Austenitic Stainless Steels. Cast austenitic alloys usually have from 5 to 20% ferrite distributed in discontinuous pools throughout the matrix, the percent of ferrite depending on the nickel, chromium, and carbon contents (see the section "Ferrite Control"). The presence of ferrite in austenite may be beneficial or detrimental, depending on the application.

Ferrite is beneficial and intentionally present in various corrosion-resistant cast steels (see some of the CF grades in Table 1, for example) to improve weldability and to maximize corrosion resistance in specific environments. Ferrite is also used for strengthening duplex alloys. The section "Austenitic-Ferritic (Duplex) Alloys" in this article gives further information.

Ferrite can be beneficial in terms of weldability because fully austenitic stainless steels are susceptible to a weldability problem known as hot cracking, or microfissuring. The intergranular cracking occurs in the weld deposit and/or in the weld heat-affected zone and can be avoided if the composition of the filler metal is controlled to produce about 4% ferrite in the austenitic weld deposit. Duplex CF grade alloy castings are immune to this problem.

The presence of ferrite in duplex CF alloys improves the resistance to stress-corrosion cracking (SCC) and generally to intergranular attack. In the case of SCC, the presence of ferrite pools in the austenite matrix is thought to block or make more difficult the propagation of cracks. In the case of intergranular corrosion, ferrite is helpful in sensitized castings because it promotes the preferential precipitation of carbides in the ferrite phase rather than at the austenite grain boundaries, where they would increase susceptibility to intergranular attack. The presence of ferrite also places additional grain boundaries in the austenite matrix, and there is evidence that intergranular attack is arrested at austenite-ferrite boundaries. It is important to note, however, that not all studies have shown ferrite to be unconditionally beneficial to the general corrosion resistance of cast stainless steels. Some solutions attack the austenite phase in heat-treated alloys, whereas others attack the ferrite. For instance, calcium chloride solutions attack the austenite. On the other hand, a 10° Baumé cornstarch solution, acidified to a pH of 1.8 with sulfuric acid and heated to a temperature of 135 °C (275 °F), attacks the ferrite. Whether corrosion resistance is improved by ferrite and to what degree depends on the specific alloy composition, the heat treatment, and the service conditions (environment and stress state).

Ferrite can be detrimental in some applications. One concern may be the reduced toughness from ferrite, although this is not a major concern, given the extremely high toughness of the austenite matrix. A much greater concern is for applications that require exposure to elevated temperatures, usually 315 °C (600 °F) and higher, where the metallurgical changes associated with the ferrite can be severe and detrimental. In applications requiring that these steels be heated in the range from 425 to 650 °C (800 to 1200 °F), carbide precipitation occurs at the edges of the ferrite pools in preference to the austenite grain boundaries. When the steel is heated above 540 °C (1000 °F), the ferrite pools transform to a χ or σ phase. If these pools are distributed in such a way that a continuous network is formed, embrittlement or a network of corrosion penetration may result. Also, if the amount of ferrite is too great, the ferrite may form continuous stringers where corrosion can take place, producing a condition similar to grain boundary attack.

In the lower end of this temperature range, the reductions in toughness observed have been attributed to carbide precipitation or reactions associated with 475 °C (885 °F) embrittlement. The 475 °C embrittlement is caused by the precipitation of an intermetallic phase with a composition of approximately 80Cr-20Fe. The name derives from the fact that this embrittlement is most severe and rapid when it occurs at approximately 475 °C (885 °F).

At 540 °C (1000 °F) and above, the ferrite phase may transform to a complex iron-chromium-nickel-molybdenum intermetallic compound known as σ phase, which reduces toughness, corrosion resistance, and creep ductility. The extent of the reduction increases with time and temperature to about 815 °C (1500 °F) and may persist to 925 °C (1700 °F). In extreme cases, Charpy V-notch energy at room temperature may be reduced 95% from its initial value (Ref 1, 2).

At temperatures above 540 °C (1000 °F), austenite also has better creep resistance than ferrite. The weaker ferrite phase may lend better plasticity to the alloy, but after long exposure at temperatures in the 540 to 760 °C (1000 to 1400 °F) range, it may transform to σ or χ phase, which reduces resistance to impact. In some instances, the alloy is deliberately aged to form the σ or χ phase and thus increase strength. Austenite can transform directly to σ or χ without going through the ferrite phase.

In weld deposits, the presence of σ or χ phase is extremely detrimental to ductility. When welding for service at room temperature or up to 540 °C (1000 °F), 4 to 10% ferrite may be present and will greatly reduce the tendency toward weld cracking. However, for service at temperatures between 540 and 815 °C (1000 and 1500 °F), the amount of ferrite in the weld must be reduced to less than 5% to avoid embrittlement from excessive σ or χ phase.

Ferrite Control. From the preceding discussion, it is apparent that ferrite in predominantly austenitic cast stainless steels can offer property advantages in some steels (notably the CF alloys) and disadvantages in other cases (primarily at elevated temperatures). The underlying causes for the dependence of ferrite content on composition are found in the phase equilibria for the iron-chromium-nickel system. These phase equilibria have been exhaustively documented and related to commercial stainless steels.

The major elemental components of cast stainless steels are in competition to promote austenite or ferrite phases in the alloy microstructure. Chromium, silicon, molybdenum, and niobium promote the presence of ferrite in the alloy microstructure; nickel, carbon, nitrogen, and manganese promote the presence of austenite. By balancing the contents of ferrite-and austenite-forming elements within the specified ranges for the elements in a given alloy, it is possible to control the amount of ferrite present in the austenite matrix. The alloy can usually be made fully austenitic or with ferrite contents up to 30% or more in the austenite matrix.

The relationship between composition and microstructure in cast stainless steels permits the foundryman to predict and control the ferrite content of an alloy, as well as its resultant properties, by adjusting the composition of the alloy. This is accomplished with the Schoefer constitution diagram for cast chromium-nickel alloys (Fig. 2). This diagram was derived from an earlier diagram developed by Schaeffler for stainless steel weld metal (Ref 1). The use of Fig. 2 requires that all ferrite-stabilizing elements in the composition be converted into chromium equivalents and that all austenite-stabilizing elements be converted into nickel equivalents by means of empirically derived coefficients representing the ferritizing or austenitizing power of each element. A composition ratio is then obtained from the total chromium equivalent, Cr_e , and nickel equivalent, Ni_e , calculated for the alloy composition by:

$$Cr_e = \%Cr + 1.5(\%Si) + 1.4(\%Mo) + \%Nb - 4.99 \quad (Eq\ 1)$$

$$Ni_e = \%Ni + 30(\%C) + 0.5 (\%Mn) + 26(\%N - 0.02) + 2.77 \quad (Eq\ 2)$$

where the elemental concentrations are given in weight percent. Although similar expressions have been derived that take into account additional alloying elements and different compositional ranges in the iron-chromium-nickel alloy system, use of the Schoefer diagram has become standard for estimating and controlling ferrite content in stainless steel castings.

Fig. 2 Schoefer diagram for estimating the ferrite content of steel castings in the composition range of 16 to 26% Cr, 6 to 14% Ni, 4% Mo (max), 1% Nb (max), 0.2% C (max), 0.19% N (max), 2% Mn (max), and 2% Si (max). Dashed lines denote scatter bands caused by the uncertainty of the chemical analysis of individual elements. See text for equations used to calculate Cr_e and Ni_e . Source: Ref 1

The Schoefer diagram possesses obvious utility for casting users and the foundryman. It is helpful for estimating or predicting ferrite content if the alloy composition is known and for setting nominal values for individual elements when calculating the furnace charge for an alloy in which a specified ferrite range is desired.

Limits of Ferrite Control. Although ferrite content can be estimated and controlled on the basis of alloy composition only, there are limits to the accuracy with which this can be done. The reasons for this are many. First, there is an unavoidable degree of uncertainty in the chemical analysis of an alloy (note the scatter band in Fig. 2). Second, in addition to composition, the ferrite content depends on thermal history, although to a lesser extent. Third, ferrite contents at different locations in individual castings can vary considerably, depending on section size, ferrite orientation, presence of alloying-element segregation, and other factors.

Both the foundryman and the user of stainless steel castings should recognize that the factors mentioned above place significant limits on the degree to which ferrite content (either as ferrite number or ferrite percentage) can be specified and controlled. In general, the accuracy of ferrite measurement and the precision of ferrite control diminish as the ferrite number increases. As a working rule, it is suggested that the ± 6 about the mean or desired ferrite number be viewed as a limit of ferrite control under ordinary circumstances, with ± 3 possible under ideal circumstances.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Heat Treatment

The heat treatment of stainless steel castings is very similar in purpose and procedure to the thermal processing of comparable wrought materials (see the article "Heat Treating of Stainless Steels" in *Heat Treating*, Volume 4 of *ASM Handbook*. However, some differences warrant separate consideration here.

Homogenization. Alloy segregation and dendritic structures may occur in castings and may be particularly pronounced in heavy sections. Because castings are not subjected to the high-temperature mechanical reduction and soaking treatments involved in the mill processing of wrought alloys, it is frequently necessary to homogenize some alloys at temperatures above 1095 °C (2000 °F) to promote uniformity of chemical composition and microstructure. The full annealing of martensitic castings results in recrystallization and maximum softness, but it is less effective than homogenization in eliminating segregation. Homogenization is a common procedure in the heat treatment of precipitation-hardening castings.

Sensitization and Solution Annealing of Austenitic and Duplex Alloys. When austenitic or duplex (ferrite in austenite matrix) stainless steels are heated in or cooled slowly through a temperature range of about 425 to 870 °C (800 to 1600 °F), chromium-rich carbides form at grain boundaries in austenitic alloys and at ferrite-austenite interfaces in duplex alloys. These carbides deplete the surrounding matrix of chromium, thus diminishing the corrosion resistance of the alloy. In small amounts, these carbides may lead to localized pitting in the alloy, but if the chromium-depleted zones are extensive throughout the alloy or heat-affected zone (HAZ) of a weld, the alloy may disintegrate intergranularly in some environments.

An alloy in this condition of reduced corrosion resistance due to the formation of chromium carbides is said to be sensitized, a situation that is most pronounced for austenitic alloys. In austenitic structures, the complex chromium carbides precipitate preferentially along the grain boundaries. This microstructure is susceptible to intergranular corrosion, especially in oxidizing solutions. In partially ferritic alloys, carbides tend to precipitate in the discontinuous carbide pools; thus, these alloys are less susceptible to intergranular attack.

Solution annealing of austenitic and duplex stainless steels makes these alloys less susceptible to intergranular attack by ensuring the complete solution of the carbides in the matrix. Depending on the specific alloy in question, temperatures between 1040 and 1205 °C (1900 and 2200 °F) will ensure the complete solution of all carbides and phases, such as σ and χ , that sometimes form in highly alloyed stainless steels. Alloys containing relatively high total alloy content, particularly high molybdenum content, often require the higher solution treatment temperature. Water quenching from the temperature range of 1040 to 1205 °C (1900 to 2200 °F) normally completes the solution treatment. Solution-annealing procedures for all austenitic alloys require holding for a sufficient amount of time to accomplish the complete solution of carbides and quenching at a rate fast enough to prevent reprecipitation of the carbides, particularly while cooling through the range of 870 to 540 °C (1600 to 1000 °F).

A two-step heat-treating procedure can be applied to the niobium-containing CF-8C alloy. The first treatment consists of solution annealing. This is followed by a stabilizing treatment at 870 to 925 °C (1600 to 1700 °F), which precipitates niobium carbides, prevents the formation of damaging chromium carbides, and provides maximum resistance to intergranular attack.

Because of their low carbon content, CF-3 and CF-3M as-cast do not contain enough chromium carbide to cause selective intergranular attack; therefore, these alloys can be used in some environments in this condition. However, for maximum corrosion resistance, these grades require solution annealing.

If the usual quenching treatment is difficult or impossible, holding for 24 to 48 h at 870 to 980 °C (1600 to 1800 °F) and air cooling is helpful for improving the resistance of castings to intergranular corrosion. However, except for alloys of

very low carbon content and castings with thin sections, this treatment fails to produce material with as good a resistance to intergranular corrosion as properly quench-annealed material.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Corrosion-Resistant Steel Castings

As previously mentioned, various high-alloy steel castings are classified as corrosion resistant (Table 1). These corrosion-resistant cast steels are widely used in chemical processing and power-generating equipment that requires corrosion resistance in aqueous or liquid-vapor environments at temperatures normally below 315 °C (600 °F). These alloys are also used in special applications with temperatures up to 650 °C (1200 °F).

Compositions

The chemical compositions of various corrosion-resistant cast steels are given in Table 1. These cast steels are specified in the ASTM standards listed in Table 1.

Straight chromium stainless steels contain 10 to 30% Cr and little or no nickel. Although about two-thirds of the corrosion-resistant steel castings produced in the United States are of grades that contain 18 to 22% Cr and 8 to 12% Ni, the straight chromium compositions are also produced in considerable quantity, particularly the steel with 11.5 to 14.0% Cr. Corrosion resistance improves as chromium content is increased. In general, intergranular corrosion is less of a concern in the straight chromium alloys (which are typically ferritic), especially those containing 25% Cr or more. This is attributed to the high bulk chromium contents and the rapid diffusion rates of chromium in ferrite.

Iron-chromium-nickel alloys have found wide acceptance and constitute about 60% of total production of high-alloy castings. They generally are austenitic with some ferrite. The most popular alloys of this type are CF-8 and CF-8M. These alloys are nominally 18-8 stainless steels are the cast counterparts of wrought types 304 and 316, respectively. The carbon content of each is maintained at 0.08% (max).

Effects of Molybdenum on Corrosion Resistance. Alloys CF-3M and CF-8M are modifications of CF-3 and CF-8 containing 2 to 3% Mo to enhance general corrosion resistance. Their passivity under weakly oxidizing conditions is more stable than that of CF-3 and CF-8. The addition of 2 to 3% Mo increases resistance to corrosion by seawater and improves resistance to many chloride-bearing environments. The presence of 2 to 3% Mo also improves crevice corrosion and pitting resistance compared to the CF-8 and CF-3 alloys. The CF-8M and CF-3M alloys have good resistance to such corrosive media as sulfurous and acetic acids and are more resistant to pitting by mild chlorides. These alloys are suitable for use in flowing seawater, but will pit under stagnant conditions.

Alloy CG-8M is slightly more highly alloyed than the CF-8M alloys, with the primary addition being increased molybdenum (3 to 4%). The increased amount of molybdenum provides superior corrosion resistance to halide-bearing media and reducing acids, particularly H₂SO₃ and H₂SO₄ solutions. The high molybdenum content, however, renders CG-8M generally unsuitable in highly oxidizing environments.

Molybdenum-bearing alloys are generally not as resistant to highly oxidizing environments (this is particularly true for boiling HNO₃), but for weakly oxidizing environments and reducing environments, Mo-bearing alloys are generally superior. Molybdenum may also produce detrimental catalytic reactions. For example, the residual molybdenum in CF-8 alloy must be held below 0.5% in the presence of hydrazine.

Effects of Chromium, Carbon, and Silicon on Corrosion Resistance. In alloys of the CF type, the effects of composition on rates of general corrosion attack have been studied, and certain definite relationships have been established. Through the use of the Huey test (five 48 h periods of exposure to boiling 65% nitric acid, as described in practice C of ASTM A 262), it has been shown that, in this standardized environment, carbide-free quench-annealed alloys of various nickel, chromium, silicon, carbon, and manganese contents have corrosion rates directly related to these contents.

Figure 3 shows the influences on corrosion rate exerted by various elements in a 19Cr-9Ni casting alloy. Variations in nickel, manganese, and nitrogen contents for the ranges shown have relatively slight influences, but variations in chromium, carbon, and silicon have marked effects. The relationship between composition and corrosion rate for properly heat-treated CF alloys in boiling 65% nitric acid is summarized in the nomograph presented in Fig. 4.

Fig. 3 Effects of various elements in a 19Cr-9Ni casting alloy on corrosion rate in boiling 65% nitric acid. Data were determined for solution-annealed and quenched specimens. Composition of base alloy was 19Cr, 9Ni, 0.09C, 0.8Mn, 1.0Si, 0.04P (max), 0.03S (max), 0.06N.

type CF casting alloys

Iron-Nickel-Chromium Alloys. For some types of service, extensive use is made of iron-nickel-chromium alloys that contain more nickel than chromium. Most important among this group is alloy CN-7M, which has a nominal composition of 28% Ni, 20% Cr, 3.5% Cu, 2.5% Mo, and 0.07% C (max). In effect, this alloy is made by adding 20% Ni and 3.5% Cu to alloy CF-8M, which greatly improves resistance to hot, concentrated, weakly oxidizing solutions such as sulfuric acid and also improves resistance to severely oxidizing media. Alloys of this type can withstand all concentrations of sulfuric acid at temperatures up to 65 °C (150 °F) and many concentrations up to 80 °C (175 °F). They are widely used in nitric-hydrofluoric pickling solutions; phosphoric acid; cold dilute hydrochloric acid; hot acetic acid; strong, hot caustic solutions; brines; and many complex plating solutions and rayon spin baths.

Results of in-plant corrosion testing of CF-8, CF-8M, and CN-7M alloys are shown in Table 3. These tests give the specific effect of molybdenum on 19Cr-9Ni alloys in reducing selective attack and pitting, and the overall corrosion rate computed from loss in weight. The higher nickel plus copper and molybdenum in the CN-7M alloy reduces the rate of corrosion to a rate lower than that of the CF-8M alloy.

Table 3 Results of in-plant corrosion testing of CF-8, CF-8M, and CN-7M alloys

Type and composition of corroding solution	Temperature of solution,		Alloy	Metal loss on surface		Surface condition by visual examination	Remarks
	°C	°F		µm/yr	mils/yr		
Neutralizer after formation of ammonium sulfate: ammonium sulfate plus small excess of sulfuric acid, ammonia vapor, and steam	100	212	CF-8	665	26.2	Very heavy etch ^(a)	CF-8M was installed for low corrosion tolerance equipment in this service and performed satisfactorily
			CF-8M	28	1.1	Light tarnish ^(b)	
			CN-7M	18	0.7	Bright	
Settling tank after neutralizer: ammonium sulfate plus excess of sulfuric acid	50	122	CF-8	385	15.2	Very heavy etch ^(a)	CF-8 in service showed excessive corrosion rate plus heavy concentration cell attack
			CF-8M	10	0.4	Slight tarnish	
			CN-7M	2.5	0.1	Bright ^(b)	
Ammonium sulfate processing solution: ammonium sulfate at pH of 8.0	50	122	CF-8	685	27.0	Heavy etch	CF-8M had too high a corrosion rate in service for good valve life, although suitable for equipment of greater corrosion tolerance. CN-7M was installed in this service
			CF-8M	175	6.8	Moderate etch	
			CN-7M	50	2.0	Light etch	
99 to 100% fuming nitric acid	20	68	CF-8	245	9.6	Moderate etch	CF-8 was satisfactory except for low-tolerance equipment such as

acid			CN-7M	79	3.1	Light etch	valves. CN-7M valves performed satisfactorily in service
			CF-8M	345	13.5	Moderate etch	
Saturated solution of sodium chloride plus 15% sodium sulfate; pH of 4.5	60	140	CF-8M	2.5	0.1	Bright	CF-8M was installed for valves in service
			CF-8	240	9.5	Concentration cell corrosion at various small areas of specimen

Corrosion From Chlorine. The influence of contaminants is one of the most important considerations in selecting an alloy for a particular process application. Ferric chloride in relatively small amounts, for example, will cause concentration cell corrosion and pitting. The buildup of corrosion products in a chloride solution may increase the iron concentration to a level high enough to be destructive. Thus, chlorine salts, wet chlorine gas, and unstable chlorinated organic compounds cannot be handled by any of the iron-base alloys, creating a need for nickel-base alloys.

Microstructures

Although corrosion-resistant cast steels are usually classified on the basis of composition, it should be recognized that classification by composition also often involves microstructural distinctions. Table 1 shows the typical microstructures of various corrosion-resistant cast steels. As noted previously, straight chromium grades of high-alloy cast steel are either martensitic or ferritic, the chromium-nickel grades are either duplex or austenitic, and the nickel-chromium steels are fully austenitic.

Martensitic grades include Alloys CA-15, CA-40, CA-15M, and CA-6NM. The CA-15 alloy contains the minimum amount of chromium necessary to make it essentially rustproof. It has good resistance to atmospheric corrosion, as well as to many organic media in relatively mild service. A higher-carbon modification of CA-15, CA-40 can be heat treated to higher strength and hardness levels. Alloy CA-15M is a molybdenum-containing modification of CA-15 that provides improved elevated-temperature strength. Alloy CA-6NM is an iron-chromium-nickel-molybdenum alloy of low carbon content.

Austenitic grades include CH-20, CK-20 and CN-7M. The CH-20 and CK-20 alloys are high-chromium, high carbon, wholly austenitic compositions in which the chromium content exceeds the nickel content. The more highly alloyed CN-7M, as described earlier in the section "Iron-Nickel-Chromium Alloys," has excellent corrosion resistance in many environments and is often used in sulfuric acid environments. The CN-7MS alloy has a corrosion resistance similar to that of CN-7M. The CN-7MS alloy has outstanding resistance to corrosion from high-strength (>90%) nitric acid.

Ferritic grades include CB-30 and CC-50. Alloy CB-30 is practically nonhardenable by heat treatment. As this alloy is normally made, the balance among the elements in the composition results in a wholly ferritic structure similar to wrought AISI type 442 stainless steel. Alloy CC-50 has substantially more chromium than CB-30 and has relatively high resistance to localized corrosion in many environments.

Austenitic-ferritic (duplex) alloys include CE-30, CF-3, CF-3A, CF-8, CF-8A, CF-20, CF-3M, CF-3MA, CF-8M, CF-8C, CF-16F, and CG-8M. The microstructures of these alloys usually contain 5 to 40% ferrite, depending on the particular grade and the balance among the ferrite-promoting and austenite-promoting elements in the chemical

composition (see the section "Ferrite Control" in this article). Duplex alloys offer superior strength, corrosion resistance, and weldability.

The use of duplex cast steels has focused primarily on the CF grades, particularly by the power generation industry. Strengthening in the cast CF grade alloys is limited essentially to that which can be gained by incorporating ferrite into the austenite matrix phase. These alloys cannot be strengthened by thermal treatment, as can the cast martensitic alloys, not by hot or cold working, as can the wrought austenitic alloys. Strengthening by carbide precipitation is also out of the question because of the detrimental effect of carbides on corrosion resistance in most aqueous environments. Thus, the alloys are effectively strengthened by balancing the alloy composition to produce a duplex microstructure consisting of ferrite (up to 40% by volume) distributed in an austenite matrix. It has been shown that the incorporation of ferrite into 19Cr-9Ni cast steels improves yield and tensile strengths without substantial loss of ductility or impact toughness at temperatures below 425 °C (800 °F). The magnitude of this strengthening effect for CF-8 and CF-8M alloys at room temperature is shown in Fig. 5. Table 4 shows the effect of ferrite content on the tensile properties of 19Cr-9Ni alloys at room temperature and at 355 °C (670 °F). Table 5 shows the effect of ferrite content on impact toughness.

Table 4 Effect of ferrite content on tensile properties of 19Cr-9Ni alloys

Ferrite content, %	Tensile strength		Yield strength at 0.2% offset		Elongation in 50 mm (2 in.), %	Reduction in area, %

Other duplex alloys of interest include CD-4MCu and Ferralium. Alloy CD-4MCu is the most highly alloyed duplex alloy. Ferralium was developed by Langley Alloys and is essentially CD-4MCu with about 0.15% N added. With high levels of ferrite (about 40 to 50%) and low nickel, the duplex alloys have better resistance to stress-corrosion cracking (SCC) than CF-3M. Alloy CD-4MCu, which contains no nitrogen and has a relatively low molybdenum content, has only

slightly better resistance to localized corrosion than CF-3M. Ferralium which has nitrogen and slightly higher molybdenum than CD-4MCu, exhibits better localized corrosion resistance than either CF-3M or CD-4MCu.

Improvements in stainless steel production practices (for example, electron beam refining, vacuum and argon-oxygen decarburization, and vacuum induction melting) have also created a second generation of duplex stainless steels. These steels offer excellent resistance to pitting and crevice corrosion, significantly better resistance to chloride SCC than the austenitic stainless steels, good toughness, and yield strengths two to three higher than those of type 304 or 316 stainless steels.

First-generation duplex stainless steels, for example, AISI type 329 and CD-4MCu, have been in use for many years. The need for improvement in the weldability and corrosion resistance of these alloys resulted in the second-generation alloys, which are characterized by the addition of nitrogen as an alloying element.

Second-generation duplex stainless steels are usually about a fifty-fifty blend of ferrite and austenite. The new duplex alloys combine the near immunity to chloride SCC of the ferritic grades with the toughness and ease of fabrication of the austenitics. Among the second-generation duplexes, Alloy 2205 seems to have become the general-purpose stainless. Table 6 lists the nominal compositions of first- and second-generation duplex alloys.

Table 6 Nominal compositions of first- and second-generation duplex stainless steels

UNS designation	Common name	Composition, % ^(a)

Precipitation-Hardening Alloys. Corrosion-resistant alloys capable of being hardened by low-temperature treatment to obtain improved mechanical properties are usually duplex-structure alloys with much more chromium than nickel. The addition of copper enables these alloys to be strengthened by precipitation hardening. These alloys are significantly higher in strength than the other corrosion-resistant alloys even without hardening.

The alloys CB-7Cu-1 and CB-7Cu-2 have corrosion resistances between those of CA-15 and CF-18. They are widely used for structural components requiring moderate corrosion resistance, as well as for components requiring resistance to erosion and wear.

The alloy CD-4MCu is widely used in many applications where its good corrosion resistance (which often equals or even exceeds that of CF-8M) and excellent resistance to erosion make it the most desirable alloy. The steel CD-4MCu has outstanding resistance to nitric acid and mixtures of nitric acid and organic acids, as well as excellent resistance to a wide range of corrosive chemical process conditions. This alloy is normally used in the solution-annealed condition, but it can be precipitation hardened for carefully selected applications when lower corrosion resistance can be tolerated and when there is no potential for stress-corrosion cracking.

Corrosion Characteristics

Table 7 compares the general corrosion resistance of the C-type (corrosion-resistant in liquid service) cast steels. Additional information on the corrosion resistance of cast steels is contained below and in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Table 7 Summary of applications for various corrosion-resistant cast steels

Alloy	Characteristics
CA-15	Widely used in mildly corrosive environments; hardenable; good erosion resistance
CA-40	Similar to CA-15 at higher strength level
CA-6NM	Improved properties over CA-15, especially improved resistance to cavitation
CA-6N	Outstanding combinations of strength, toughness, and weldability with moderately good corrosion resistance
CB-30	Improved performance in oxidizing environments compared to CA-15; excellent resistance to corrosion by nitric acid, alkaline solutions, and many organic chemicals
CB-7Cu-1	Hardenable with good corrosion resistance
CB-7Cu-2	Superior combination of strength, toughness, and weldability with moderately good corrosion resistance
CC-50	Used in highly oxidizing media (hot HNO ₃ , acid mine waters)
CD-4MCu	Similar to CF-8 in corrosion resistance, but higher strength, hardness, and stress-corrosion cracking resistance; excellent resistance to environments involving abrasion or erosion-corrosion; usefully

	employed in handling both oxidizing and reducing corrodents
CE-30	Similar to CC-50, but Ni imparts higher strength and toughness levels. A grade available with controlled ferrite
CF-3, CF-8, CF-20, CF-3M, CF-8M, CF-8C, CF-16F	CF types: most widely used corrosion-resistant alloys at ambient and cryogenic temperatures
	M variations: enhanced resistance to halogen ion and reducing acids
	C and F variations: used where application does not permit postweld heat treat
	A grades available with controlled ferrite
CG-8M	Greater resistance to pitting and corrosion in reducing media than CF-8M; not suitable for nitric acids or other strongly oxidizing environments
CH-20	Superior to CF-8 in specialized chemical and paper application in resistance to hot H_2SO_3 , organic acids, and dilute H_2SO_4 ; the high nickel and chromium contents also make this alloy less susceptible to intergranular corrosion after exposure to carbide-precipitating temperatures
CK-20	Improved corrosion resistance compared to CH-20
CN-7M	Highly resistant to H_2SO_4 , H_3PO_4 , H_2SO_3 salts, and seawater. Good resistance to hot chloride salt solutions, nitric acid, and many reducing chemicals

General Corrosion of Martensitic Alloys. The martensitic grades include CA-15, CA-15M, CA-6NM, CA-6NM-B, CA-40, CB-7Cu1, and CB-7Cu-2. These alloys are generally used in applications requiring high strength and some corrosion resistance.

Alloy CA-15 typically exhibits a microstructure of martensite and ferrite. This alloy contains the minimum amount of chromium to be considered a stainless steel (11 to 14% Cr) and as such may not be used in aggressive environments. It does, however exhibit good atmospheric-corrosion resistance and it resists staining by many organic environments. Alloy CA-15M may contain slightly more molybdenum than CA-15 (up to 1% Mo) and therefore may have improved general corrosion resistance in relatively mild environments. Alloy CA-6NM is similar to CA-15M except that it contains more nickel and molybdenum, thereby improving its general corrosion resistance. Alloy CA-6NM-B is a lower-carbon version of this alloy. The lower strength level promotes resistance to sulfide stress cracking. Alloy CA-40 is a higher-strength version of CA-15 and it, too, exhibits excellent atmospheric-corrosion resistance after a normalize and temper heat treatment. Microstructurally, the CB-7Cu alloys usually consist of mixed martensite and ferrite and, because of the increased chromium and nickel levels compared to the other martensitic alloys, they offer improved corrosion resistance to seawater and some mild acids. These alloys also have good atmospheric-corrosion resistance. The CB-7Cu alloys are hardenable and offer the possibility of increased strength and improved corrosion resistance among the martensitic alloys.

General Corrosion of Ferritic Alloys. Alloys CB-30 and CC-50 are higher-carbon and higher-chromium alloys than are the CA alloys mentioned above. Each alloy is predominantly ferritic, although a small amount of martensite may be found in CB-30. Alloy CB-30 contains 18 to 21% Cr and is used in chemical processing and oil refining applications. The chromium content is sufficient to have good corrosion resistance to many acids, including nitric acid (HNO_3).

General Corrosion of Austenitic and Duplex Alloys. Alloy CF-8 may be fully austenitic, but it more commonly contains some residual ferrite (3 to 30%) in an austenite matrix. In the solution-annealed condition, this alloy has excellent resistance to a wide variety of acids. It is particularly resistant to highly oxidizing acids, such as boiling HNO_3 . The duplex nature of the microstructure of this alloy imparts additional resistance to SCC compared to its wholly

austenitic counterparts. Alloy CF-3 is a reduced-carbon version of CF-8 with essentially identical corrosion resistance except that CF-3 is much less susceptible to sensitization. For applications in which the corrosion resistance of the weld HAZ may be critical, CF-3 is a common material selection.

Alloys CF-8A and CF-3A contain more ferrite than their CF-8 and CF-3 counterparts. Because the higher ferrite content is achieved by increasing the chromium/nickel equivalent ratio, the CF-8A and CF-3A alloys may have slightly higher chromium or slightly lower nickel contents than the low-ferrite equivalents. In general, the corrosion resistance is very similar, but the strength increases with ferrite content. Because of the high ferrite content, service should be restricted to temperatures below 400 °C (750 °F) because of the possibility of severe embrittlement. Alloy CF-8C is the niobium-stabilized grade of the CF-8 alloy class. This alloy contains small amounts of niobium, which tend to form carbides preferentially over chromium carbides and improve intergranular corrosion resistance in applications involving relatively high service temperatures.

Alloy CF-16F is a selenium-bearing free-machining grade of cast stainless steel. Because CF-16F nominally contains 19% Cr and 10% Ni, it has adequate corrosion resistance to a wide range of corrosive materials but the large number of selenide inclusions makes surface deterioration and pitting definite possibilities.

Alloy CE-30 is a nominally 27Cr-9Ni alloy that normally contains 10 to 20% ferrite in an austenite matrix. The high carbon, high ferrite content provides relatively high strength. The high chromium content and duplex structure act to minimize corrosion because of the formation of chromium carbides in the microstructure. This particular alloy is known for good resistance to sulfurous acid and sulfuric acid and is used extensively in the pulp and paper industry (see the article "Corrosion in the Pulp and Paper Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

Alloy CD-4MCu is the most highly alloyed material in this group of alloys, and a microstructure containing approximately equal amounts of ferrite and austenite is common. The low carbon content and high chromium content render the alloy relatively immune to intergranular corrosion. High chromium and molybdenum provide a high degree of localized corrosion resistance (crevices and pitting), and the duplex microstructure provides SCC resistance in many environments. This alloy can be precipitation hardened to provide strength and is also relatively resistant to abrasion and erosion-corrosion.

Fully Austenitic Alloys. Alloys CH-10 and CH-20 are fully austenitic and contain 22 to 26% Cr and 12 to 15% Ni. The high chromium content minimizes the tendency toward the formation of chromium-depleted zones due to sensitization. These alloys are used for handling paper pulp solutions and are known for good resistance to dilute H₂SO₄ and HNO₃.

Alloy CK-20 contains 23 to 27% Cr and 19 to 22% Ni and is less susceptible than CH-20 to intergranular corrosion attack in many acids after brief exposures to the chromium carbide formation temperature range. Maximum corrosion resistance is achieved by solution treatment. Alloy CK-20 possesses good corrosion resistance to many acids and, because of its fully austenitic structure, can be used at relatively high temperatures.

Alloy CN-7M exhibits excellent corrosion resistance in a wide variety of environments and is often used for H₂SO₄ service. Relatively high resistance to intergranular corrosion and SCC make this alloy attractive for many applications. Although CN-7M is relatively highly alloyed, its fully austenitic structure may lead to SCC susceptibility for some environments and stress states.

Alloy CF-20 is a fully austenitic, relatively high-strength corrosion-resistant alloy. The 19% Cr content provides resistance to many types of oxidizing acids, but the high carbon content makes it imperative that this alloy be used in the solution-treated condition for environments known to cause intergranular corrosion.

Intergranular Corrosion. Ferritic alloys may also be sensitized by the formation of extensive chromium carbide networks, but because of the high bulk chromium content and rapid diffusion rates of chromium in ferrite, the formation of carbides can be tolerated if the alloy has been slowly cooled from a solutionizing temperature of 780 to 900 °C (1435 to 1650 °F). The slow cooling allows replenishment of the chromium adjacent to the carbides. Martensitic alloys normally do not contain sufficient bulk chromium to be used in applications in which intergranular corrosion is likely to be a concern.

Austenitic and duplex stainless steels use solution annealing for the prevention or reduction of intergranular corrosion (see "Sensitization and Solution Annealing of Austenitic and Duplex Alloys" in this article). Failure to solution treat a particular alloy or an improper solution treatment may seriously compromise the observed corrosion resistance in service.

If solution treatment of the alloy after casting and/or welding is impractical or impossible, the metallurgist has several tools from which to choose to minimize potential intergranular corrosion problems. The low-carbon grades CF-3 and CF-3M are commonly used when heat treatment is impractical or as a solution to the sensitization incurred during welding. The low carbon content, that is, 0.03% C (max), of these alloys precludes the formation of an extensive number of chromium carbides. In addition, these alloys normally contain 3 to 30% ferrite in an austenitic matrix. By virtue of rapid carbide precipitation kinetics at ferrite/austenite interfaces compared to austenite/austenite interfaces, carbide precipitation is confined to ferrite-austenite boundaries in alloys containing a minimum of about 3 to 5% ferrite (Ref 4, 5). If the ferrite network is discontinuous in the austenite matrix (depending on the amount, size, and distribution of ferrite pools), extensive intergranular corrosion will not be a problem in most of the environments to which these alloys will be subjected.

The niobium-modified grade of 18-8, known as CF-89C, is produced for similar applications in which heat treatment is impractical. Niobium-containing alloys that have been heated to sensitizing temperatures around 650 °C (1200 °F) are not susceptible to intergranular corrosion. However, they are more susceptible to overall corrosion when tested in nitric acid, compared to the niobium-free, quench-annealed alloys of the same nickel, chromium, and carbon contents. Addition of niobium to molybdenum-containing type CF alloys has also been found unsatisfactory for castings. When both niobium and molybdenum are present, the ferrite phase tends to form as an interconnected network and is especially likely to transform into the brittle σ phase. As a result, castings in the as-cast condition become embrittled and have a tendency to crack.

When the niobium-bearing grade CF-8C is in the as-cast condition, most of its carbon is in the form of niobium carbide, precluding chromium carbide precipitation in the critical temperature range from 425 to 870 °C (800 to 1600 °F) and particularly from 565 to 650 °C (1050 to 1200 °F). The alloy CF-8C is solution treated at 1120 °C (2050 °F), quenched to room temperature, and then reheated to 870 to 925 °C (1600 to 1700 °F), at which temperature precipitation of niobium carbide occurs. An alternative method is solution treating at 1120 °C (2050 °F), cooling to the 870 to 925 °C (1600 to 1700 °F) range, and then holding at this temperature before cooling to room temperature. For maximum corrosion resistance, it is recommended that this alloy be solution treated before being stabilized.

Weld crack sensitivity of CF alloys containing niobium (CF-8C) is more pronounced in the fully austenitic grade. Cracking may be alleviated through the introduction into the weld deposit of a small amount of ferrite, usually between 4 and 10%. However, appreciable amounts of ferrite in niobium-bearing corrosion-resistant steels will transform, at least partly, to the σ or χ phase upon heating to between 540 and 925 °C (1000 and 1700 °F).

Stress-Corrosion Cracking. The SCC of cast stainless steels has been investigated for only a limited number of environments, heat treatments, and test conditions. From the limited information available, the following generalizations apply.

First, SCC resistance seems to improve as the composition is adjusted to provide increasingly greater amounts of ferrite in an austenitic matrix. This trend continues to a certain level, apparently near 50% ferrite (Fig. 6). Second, a lower nickel content tends to improve SCC resistance in cast duplex alloys, possibly because of its effect on ferrite content (Ref 6). Third, ferrite appears to be involved in a keying action in discouraging SCC. At low and medium stress levels, the ferrite tends to block the propagation of stress-corrosion cracks. This may be due to a change in composition and/or crystal structure across the austenite/ferrite boundary. As the stress level increases, crack propagation may change from austenite/ferrite boundaries to transgranular propagation (Ref 6, 7). Finally, reducing the carbon content of cast stainless alloys, thereby reducing the susceptibility to sensitization, improves SCC resistance. This is also true for wrought alloys.

Fig. 6 Stress required to produce stress-corrosion cracking in several corrosion-resistant cast steels with varying amounts of ferrite

Mechanical Properties of Corrosion-Resistant Cast Steels

The importance of mechanical properties in the selection of corrosion-resistant cast steels is established by the casting application. The paramount basis for alloy selection is normally the resistance of the alloy to the specific corrosive media or environment of interest. The mechanical properties of the alloy are usually, but not always, secondary considerations in these applications.

Room-Temperature Mechanical Properties. Representative room-temperature tensile properties, hardness, and Charpy impact values for corrosion-resistant cast steels are given in Fig. 7. These properties are representative of the alloys rather than the specification requirements. Minimum specified mechanical properties for these alloys are given in ASTM standards A 351, A 743, A 744, and A 747. A wide range of mechanical properties are attainable depending on the selection of alloy composition and heat treatment. Tensile strengths ranging from 475 to 1310 MPa (69 to 190 ksi) and hardness from 130 to 400 HB are available among the cast corrosion-resistant alloys. Similarly, wide ranges exist in yield strength, elongation, and impact toughness.

Fig. 7 Mechanical properties of various cast corrosion-resistant steels at room temperature. (a) Tensile strength. (b) 0.2% offset yield strength. (b) 0.2% offset yield strength. (c) Charpy keyhole impact energy. (d) Brinell hardness. (e) Elongation. Also given are the heat treatments used for test materials: AC, air cool; FC, furnace cool; WQ, water quench; A, anneal; T, temper.

The straight chromium steels (CA-15, CA-40, CB-30, and CC-50) possess either martensitic or ferritic microstructures in the end-use condition (Table 1). The CA-15 and CA-40 alloys, which contain nominally 12% Cr, are hardenable through heat treatment by means of the martensite transformation and are of the selected as much or more for their high strength as for their comparatively modest corrosion resistance.

The higher-chromium CB-30 and CC-50 alloys, on the other hand, are fully ferritic alloys that are not hardenable by heat treatment. These alloys are generally used in the annealed condition and exhibit moderate tensile properties and hardness. Like most ferritic alloys, CB-30 and CC-50 possess limited impact toughness, especially at low temperatures.

Three chromium-nickel alloys, CA-6NM, CB-7Cu, and CD-4M Cu, are exceptional in their response to heat treatment and in the resultant mechanical properties. Alloy CA-6NM is balanced compositionally for martensitic hardening response. This alloy was developed as an alternative to CA-15 and has improved impact toughness and weldability. The CB-7Cu and CD-4MCu alloys both contain copper and can be strengthened by age hardening. These alloys are initially solution heat treated and then cooled rapidly (usually by quenching in oil or water); thus, the phases that would normally precipitate at slow cooling rates cannot form. The casting is then heated to an intermediate aging temperature at which the precipitation reaction can occur under controlled conditions until the desired combination of strength and other properties is achieved. The CB-7Cu alloy possesses a martensitic matrix, while the CD-4MCu alloy possesses a duplex microstructure, consisting of approximately 40% austenite in a ferritic matrix. Alloy CB-7 Cu is applied in the aged condition to obtain the benefit of its excellent combination of strength and corrosion resistance, but alloy CD-4MCu is seldom applied in the aged condition because of its relatively low resistance to SCC in this condition compared to its superior corrosion resistance in the solution-annealed condition.

The CE, CF, CG, CH, CN, and CK alloys are essentially not hardenable by heat treatment. To ensure maximum corrosion resistance, however, it is necessary that castings of these grades receive a high-temperature solution anneal (see "Sensitization and Solution Annealing of Austenitic and Duplex Alloys" in this article). By virtue of their microstructures, which are fully austenitic or duplex without significant carbide precipitation, the alloys exhibit generally excellent impact toughness at low temperatures. The tensile strength range represented by these alloys typically extends from 475 to 670 MPa (69 to 97 ksi). As indicated earlier in the section "Austenitic-Ferritic (Duplex) Alloys" in this article, the alloys with duplex structures can be strengthened by balancing the composition for higher ferrite levels (Fig. 5). The tensile and yield strengths of CF alloys with a ferrite number of 35 are typically 150 MPa (22 ksi) higher than those of fully austenitic alloys. Tensile ductility (Table 4) and impact toughness (Table 5) are lowered with increasing ferrite content.

Effects from High Temperatures. Cast corrosion-resistant high-alloy steels are used extensively at moderately elevated temperatures (up to 650 °C, or 1200 °F). Elevated-temperature properties are important selection criteria for these applications. Table 8 gives the tensile properties of a corrosion-resistant cast steel at various test temperatures. In addition, mechanical properties after long-term exposure at elevated temperatures are increasingly considered because of the aging effect that these exposures may have. For example, cast alloys CF-8C, CF-8M, CE-30A, and CA-15 are currently used in high-pressure service at temperatures up to 540 °C (1000 °F) in sulfurous acid environments in the petro-chemical industry. Other uses are in the power-generating industry at temperatures up to 565 °C (1050 °F).

Table 8 Short-time tensile properties of peripheral-welded cylinders of CF-8 alloy

Cylinders were 38 mm (1 ¹/₂ in.) thick; specimens were machined with longitudinal axes perpendicular to welded seam and with seam at middle of gage length.

(b) Separately cast from same heat as cylinders

Room-temperature properties after exposure to elevated service temperatures may differ from those in the as-heat-treated condition because of the microstructural changes that may take place at the service temperature. Microstructural changes in iron-nickel-chromium-(molybdenum) alloys may involve the formation of carbides and such phases as σ , χ , and η (Laves). The extent to which these phases form depends on the composition, as well as the time at elevated temperature.

The martensitic alloys CA-15 and CA-6NM are subject to minor changes in mechanical properties and SCC resistance in NaCl and polythionic acid environments upon exposure for 3000 h at up to 565 °C (1050 °F). In CF-type chromium-nickel-(molybdenum) steels, only negligible changes in ferrite content occur during 10,000 h exposure at 400 °C (750 °F) and during 3000 h exposure at 425 °C (800 °F). Carbide precipitation, however, does occur at these temperatures, and noticeable Charpy V-notch energy losses have been reported.

Above 425 °C (800 °F), microstructural changes in chromium-nickel-(molybdenum) alloys take place at an increased rate. Carbides and σ phase form rapidly at 650 °C (1200 °F) at the expense of ferrite. Tensile ductility and Charpy V-

notch impact energy (Fig. 8) are prone to significant losses under these conditions. Density changes, resulting in contraction, have been reported as a result of these high-temperature exposures.

Fig. 8 Charpy V-notch impact energy of three corrosion-resistant cast steels at room temperature after aging at 594 °C (1100 °F). Source: Ref 8

Fatigue Properties and Corrosion Fatigue. The resistance of cast stainless steels to fatigue depends on a sizable number of material, design, and environmental factors. For example, design factors of importance include the stress distribution within the casting (residual and applied stresses), the location and severity of stress concentrators (surface integrity), and the environment and service temperatures. Material factors of importance include strength and microstructure. It is generally found that fatigue strength increases with the tensile strength of a material. Both fatigue strength and tensile strength usually increase with decreasing temperature. Under equivalent conditions of stress, stress concentration, and strength, evidence suggests that austenitic materials are less notch sensitive than martensitic or ferritic materials.

Corrosion fatigue is highly specific to the environment and alloy. The martensitic materials are degraded the most in both absolute and relative terms. If left to corrode freely in seawater, they have very little resistance to corrosion fatigue. This is remarkable in view of their very high strength and fatigue resistance in air.

Properties can be protected if suitable cathodic protection is applied. However, because these materials are susceptible to hydrogen embrittlement, cathodic protection must be carefully applied. Too large a protective potential will lead to catastrophic hydrogen stress cracking.

Austenitic materials are also severely degraded in corrosion fatigue strength under conditions conducive to pitting, such as in seawater. However, they are easily cathodically protected without fear of hydrogen embrittlement and perform well in fresh waters. The corrosion fatigue behavior of duplex alloys has not been widely studied.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Heat-Resistant Cast Steels

As previously mentioned, castings are classified as heat resistant if they are capable of sustained operation while exposed, either continuously or intermittently, to operating temperatures that result in metal temperatures in excess of 650 °C (1200 °F). Cast steels for this type of service include iron-chromium (straight chromium), iron-chromium-nickel, and iron-nickel-chromium alloys. In applications of heat-resistant alloys, considerations include:

- Resistance to corrosion at elevated temperatures
- Stability (resistance to warping, cracking, or thermal fatigue)
- Creep strength (resistance to plastic flow)

Table 9 briefly compares the various H-type grades of heat-resistant steel castings in terms of general corrosion resistance and creep values.

Table 9 General corrosion characteristics of heat-resistant cast steels and typical limiting creep stress values at indicated temperatures

Alloy	Corrosion characteristics	Creep test temperature		Limiting creep stress (0.0001%/h)	
		°C	°F	MPa	ksi
HA	Good oxidation resistance to 650 °C (1200 °F); widely used in oil refining industry	650	1200	21.5	3.1

HC	Good sulfur and oxidation resistance up to 1095 °C (2000 °F); minimal mechanical properties; used in applications where strength is not a consideration or for moderate load bearing up to 650 °C (1200 °F)	870	1600	5.15	0.75
HD	Excellent oxidation and sulfur resistance plus weldability	980	1800	6.2	0.9
HE	Higher temperature and sulfur resistance capabilities than HD	980	1800	9.5	1.4
HF	Excellent general corrosion resistance to 815 °C (1500 °F) with moderate mechanical properties	870	1600	27	3.9
HH ^(a)	High strength; oxidation resistant to 1090 °C (2000 °F); most widely used	980	1800	7.5 (type I) 14.5 (type II)	1.1 (type I) 2.1 (type II)
HI	Improved oxidation resistance compared to HH	980	1800	13	1.9
HK	Because of its high temperature strength, widely used for stressed parts in structural applications up to 1150 °C (2100 °F); offers good resistance to corrosion by hot gases, including sulfur-bearing gases, in both oxidizing and reducing conditions (although HC, HE, and HI are more resistant in oxidizing gases); used in air, ammonia, hydrogen, and molten neutral salts; widely used for tubes and furnace parts	1040	1900	9.5	1.4
HL	Improved sulfur resistance compared to HK; especially useful where excessive scaling must be avoided	980	1800	15	2.2
HN	Very high strength at high temperatures; resistant to oxidizing and reducing flue gases	1040	1900	11	1.6
HP	Resistant to both oxidizing and carburizing atmospheres at high temperatures	980	1800	19	2.8
HP-50WZ	Improved creep rupture strength at 1090 °C (2000 °F) and above compared to HP	1090	2000	4.8	0.7
HT	Widely used in thermal shock applications; corrosion resistant in air, oxidizing and reducing flue gases, carburizing gases, salts, and molten metals; performs satisfactorily up to 1150 °C (2100 °F) in oxidizing atmospheres and up to 1095 °C (2000 °F) in reducing atmospheres, provided that limiting creep stress values are not exceeded	980	1800	14	2.0
HU	Higher hot strength than HT and often selected for its superior corrosion resistance	980	1800	15	2.2
HW	High hot strength and electrical resistivity; performs satisfactorily to 1120 °C (2050 °F) in strongly oxidizing atmospheres and up to 1040 °C (1900 °F) in oxidizing or reducing products of combustion that do not contain sulfur; resistant to some salts and molten metals	980	1800	9.5	1.4
HX	Resistant to hot-gas corrosion under cycling conditions without cracking or warping; corrosion resistant in air, carburizing gases, combustion gases, flue gases, hydrogen,	980	1800	11	1.6

	molten cyanide, molten lead, and molten neutral salts at temperatures up to 1150 °C (2100 °F)				
--	--	--	--	--	--

(a) Two grades: type I (ferrite in austenite) and type II (wholly austenitic), per ASTM A 447

Commercial applications of heat-resistant castings include metal treatment furnaces, gas turbines, aircraft engines, military equipment, oil refinery furnaces, cement mill equipment, petrochemical furnaces, chemical process equipment, power plant equipment, steel mill equipment, turbochargers, and equipment used in manufacturing glass and synthetic rubber. Alloys of the iron-chromium and iron-chromium-nickel groups are of the greatest commercial importance.

General Properties

General corrosion and creep properties of heat-resistant steel castings are compared in Table 8. The compositions of these heat-resistant cast steels are given in Table 2. These heat-resistant cast steels resemble corrosion-resistant cast steels (Table 1) except for their higher carbon content, which imparts greater strength at elevated temperatures. Typical tensile properties of heat-resistant cast steels at room temperature are given in Table 10 and (at elevated temperatures) in Table 11.

(a) In this instance, test temperature was 540 °C (1000 °F).

(b) Test temperature was 590 °C (1100 °F).

(c) Type I and II per ASTM A 447

(d) Test temperature was 650 °C (1200 °F).

Iron-chromium alloys contain 10 to 30% Cr and little or no nickel. These alloys are useful chiefly for resistance to oxidation; they have low strength at elevated temperatures. Use of these alloys is restricted to conditions, either oxidizing or reducing, that involve low static loads and uniform heating. Chromium content depends on anticipated service temperature.

Iron-chromium-nickel alloys contain more than 13% Cr and more than 7% Ni (always more chromium than nickel). These austenitic alloys are ordinarily used under oxidizing or reducing conditions similar to those withstood by the ferritic iron-chromium alloys, but in service they have greater strength and ductility than the straight chromium alloys. They are used, therefore, to withstand greater loads and moderate changes of temperature. These alloys also are used in the presence of oxidizing and reducing gases that are high in sulfur content.

Iron-nickel-chromium alloys contain more than 25% Ni and more than 10% Cr (always more nickel than chromium). These austenitic alloys are used for withstanding reduction as well as oxidizing atmospheres, except where sulfur content is appreciable. (In atmospheres containing 0.05% or more hydrogen sulfide, for example, iron-chromium-nickel alloys are recommended.) In contrast with iron-chromium-nickel alloys, iron-nickel-chromium alloys do not carburize rapidly or become brittle and do not take up nitrogen in nitriding atmospheres. These characteristics become enhanced as nickel content is increased, and in carburizing and nitriding atmospheres casting life increases with nickel content. Austenitic iron-nickel-chromium alloys are used extensively under conditions of severe temperature fluctuations such as those encountered by fixtures used in quenching and by parts that are not heated uniformly or that are heated and cooled intermittently. In addition, these alloys have characteristics that make them suitable for electrical resistance heating elements.

Metallurgical Structures

The structures of chromium-nickel and nickel-chromium cast steels must be wholly austenitic, or mostly austenitic with some ferrite, if these alloys are to be used for heat-resistant service. Depending on the chromium and nickel content (see the section "Composition and Microstructure" in this article), the structures of these iron-base alloys can be austenitic (stable), ferritic (stable, but also soft, weak, and ductile) or martensitic (unstable); therefore, chromium and nickel levels should be selected to achieve good strength at elevated temperatures combined with resistance to carburization and hot-gas corrosion.

A fine dispersion of carbides or intermetallic compounds in an austenitic matrix increases high-temperature strength considerably. For this reason, heat-resistant cast steels are higher in carbon content than are corrosion-resistant alloys of comparable chromium and nickel content. By holding at temperatures where carbon diffusion is rapid (such as above 1200 °C) and then rapidly cooling, a high and uniform carbon content is established, and up to about 0.20% C is retained in the austenite. Some chromium carbides are present in the structures of alloys with carbon contents greater than 0.20%, regardless of solution treatment, as described in the section "Sensitization and Solution Annealing of Austenitic and Duplex Alloys" in this article.

Castings develop considerable segregation as they freeze. In standard grades, either in the as-cast condition or after rapid cooling from a temperature near the melting point, much of the carbon is in supersaturated solid solution. Subsequent reheating precipitates excess carbides. The lower the reheating temperature, the slower the reaction and the finer the precipitated carbides. Fine carbides increase creep strength and decrease ductility. Intermetallic compounds such as Ni₃Al, if present, have a similar effect.

Reheating material containing precipitated carbides in the range between 980 and 1200 °C (1800 and 2200 °F) will agglomerate and spheroidize the carbides, which reduces creep strength and increases ductility. Above 1100 °C (2000 °F), so many of the fine carbides are dissolved or spheroidized that this strengthening mechanism loses its importance. For service above 1100 °C (2000 °F), certain proprietary alloys of the iron-nickel-chromium type have been developed. Alloys for this service contain tungsten to form tungsten carbides, which are more stable than chromium carbides at these temperatures.

Aging at a low temperature, such as 760 °C (1400 °F), where a fine, uniformly dispersed carbide precipitate will form, confers a high level of strength that is retained at temperatures up to those at which agglomeration changes the character of the carbide dispersion (overaging temperatures). Solution heat treatment or quench annealing, followed by aging, is the treatment generally employed to attain maximum creep strength.

Ductility is usually reduced when strengthening occurs; but in some alloys the strengthening treatment correct an unfavorable grain-boundary network of brittle carbides, and both properties benefit. However, such treatment is costly and may warp castings excessively. Hence, this treatment is applied to heat-resistant castings only for the small percentage of applications for which the need for premium performance justifies the high cost.

Carbide networks at grain boundaries are generally undesirable in iron-base heat-resistant alloys. Grain-boundary networks usually occur in very-high-carbon alloys or in alloys that have cooled slowly through the high-temperature ranges in which excess carbon in the austenite is rejected as grain-boundary networks rather than as dispersed particles. These networks confer brittleness in proportion to their continuity.

Carbide networks also provide paths for selective attack in some atmospheres and in certain molten salts. Therefore, it is advisable in some salt bath applications to sacrifice the high-temperature strength imparted by high carbon content and gain resistance to intergranular corrosion by specifying that carbon content be no greater than 0.08%.

Straight Chromium Heat-Resistant Castings

Iron-chromium alloys, also known as straight chromium alloys, contain either 9 or 28% Cr. HC and HD alloys are included among the straight chromium alloys, although they contain low levels of nickel.

HA alloy (9Cr-1Mo), a heat treatable material, contains enough chromium to provide good resistance to oxidation at temperatures up to about 650 °C (1200 °F). The 1% molybdenum is present to provide increased strength. HA alloy castings are widely used in oil refinery service. A higher-chromium modification of this alloy (12 to 14% Cr) is widely used in the glass industry.

HA alloy has a structure that is essentially ferritic; carbides are present in pearlitic areas or as agglomerated particles, depending on prior heat treatment. Hardening of the alloy occurs upon cooling in air from temperatures above 815 °C (1500 °F). In the normalized and tempered condition, the alloy exhibits satisfactory toughness throughout its useful temperature range.

HC alloy (28% Cr) resists oxidation and the effects of high-sulfur flue gases at temperatures up to 1100 °C (2000 °F). It is used for applications in which strength is not a consideration, or in which only moderate loads are involved, at temperatures of about 650 °C (1200 °F). It is also used where appreciable nickel cannot be tolerated, as in very-high-sulfur atmospheres, or where nickel may act as an undesirable catalyst and destroy hydrocarbons by causing them to crack.

HC alloy is ferritic at all temperatures. Its ductility and impact strength are very low at room temperature and its creep strength is very low at elevated temperatures unless some nickel is present. In a variation of HC alloy that contains more than 2% Ni, substantial improvement in all three of these properties is obtained by increasing the nitrogen content to 0.15% or more.

HC alloy becomes embrittled when heated for prolonged periods at temperatures between 400 and 550 °C (750 and 1025 °F), and it shows low resistance to impact. The alloy is magnetic and has a low coefficient of thermal expansion, comparable to that of carbon steel. It has about eight times the electrical resistivity and about half the thermal conductivity of carbon steel. Its thermal conductivity, however, is roughly double the value for austenitic iron-chromium-nickel alloys.

HD alloy (28Cr-5Ni) is very similar in general properties to HC, except that its nickel content gives it somewhat greater strength at high temperatures. The high chromium content of this alloy makes it suitable for use in high-sulfur atmospheres.

HD alloy has a two-phase, ferrite-plus-austenite structure that is not hardenable by conventional heat treatment. Long exposure at 700 to 900 °C (1300 to 1650 °F), however, may result in considerable hardening and severe loss of room-temperature ductility through the formation of σ phase. Ductility may be restored by heating uniformly to 980 °C (1800 °F) or higher and then cooling rapidly to below 650 °C (1200 °F).

Iron-Chromium-Nickel Heat-Resistant Castings

Heat-resistant ferrous alloys in which the chromium content exceeds the nickel content are made in compositions ranging from 20Cr-10Ni to 30Cr-20Ni.

HE alloy (28Cr-10Ni) has excellent resistance to corrosion at elevated temperatures. Because of its higher chromium content, it can be used at higher temperatures than HF alloy and is suitable for applications up to 1100 °C (2000 °F). This alloy is stronger and more ductile at room temperature than the straight chromium alloys.

In the as-cast condition, HE alloy has a two-phase, austenite-plus-ferrite structure containing carbides. HE castings cannot be hardened by heat treatment; however, as with HD castings, long exposure to temperatures near 815 °C (1500 °F) will promote formation of σ phase and consequent embrittlement of the alloy at room temperature. The ductility of this alloy can be improved somewhat by quenching from about 1100 °C (2000 °F).

Castings of HE alloy have good machining and welding properties. Thermal expansion is about 50% greater than that of either carbon steel or the Fe-Cr alloy HC. Thermal conductivity is much lower than for HD or HC, but electrical resistivity is about the same. HE alloy is weakly magnetic.

HF alloy (20Cr-10Ni) is the cast version of 18-8 stainless steel, which is widely used for its outstanding resistance to corrosion. HF alloy is suitable for use at temperatures up to 870 °C (1600 °F). When this alloy is used for resistance to oxidation at elevated temperatures, it is not necessary to keep the carbon content at the low level specified for corrosion-resistant castings. Molybdenum, tungsten, niobium, and titanium are sometimes added to the basic HF composition to improve elevated-temperature strength.

In the as-cast condition, HF alloy has an austenitic matrix that contains interdendritic eutectic carbides and, occasionally, a lamellar constituent presumed to consist of alternating platelets of austenite and carbide or carbonitride. Exposure at service temperatures usually promotes precipitation of finely dispersed carbides, which increases room-temperature strength and causes some loss of ductility. If improperly balanced, as-cast HF may be partly ferritic. HF is susceptible to embrittlement due to σ -phase formation after long exposure at 760 to 815 °C (1400 to 1500 °F).

HH Alloy (26Cr-12Ni). Alloys of this nominal composition comprise about one-third of the total production of iron-base heat-resistant castings. Alloy HH is basically austenitic and holds considerable carbon in solid solution, but carbides, ferrite (soft, ductile, and magnetic) and σ (hard, brittle, and nonmagnetic) may also be present in the microstructure. The amounts of the various structural constituents present depend on composition and thermal history. In fact, two distinct grades of material can be obtained within the stated chemical compositional range of the type alloy HH. These grades are defined as type I (partially ferritic) and type II (wholly austenitic) in ASTM A 447.

The partially ferritic (type I) alloy HH is adapted to operating conditions that are subject to changes in temperature level and applied stress. A plastic extension in the weaker, ductile ferrite under changing load tends to occur more readily than in the stronger austenitic phase, thereby reducing unit stresses and stress concentrations and permitting rapid adjustment to suddenly applied overloads without cracking. Near 870 °C (1600 °F), the partially ferritic alloys tend to embrittle from the development of σ phase, while close to 760 °C (1400 °F), carbide precipitation may cause comparable loss of ductility. Such possible embrittlement suggests that 930 to 1090 °C (1700 to 2000 °F) is the best service temperature range, but this is not critical for steady temperature conditions in the absence of unusual thermal or mechanical stresses.

To achieve maximum strength at elevated temperatures, the HH alloy must be wholly austenitic. Where load and temperature conditions are comparatively constant, the wholly austenitic (type II) alloy HH provides the highest creep strength and permits the use of maximum design stress. The stable austenitic alloy is also favored for cyclic temperature service that might induce σ -phase formation in the partially ferritic type. When HH alloy is heated to between 650 and 870 °C (1200 and 1600 °F), a loss in ductility may be produced by either of two changes within the alloy: precipitation of carbides or transformation of ferrite to σ . When the composition is balanced so that the structure is wholly austenitic, only carbide precipitation normally occurs. In partly ferritic alloys, both carbides and σ phase may form.

The wholly austenitic (type II) HH alloy is used extensively in high-temperature applications because of its combination of relatively high strength and oxidation resistance at temperatures up to 1100 °C (2000 °F). Typical tensile properties and impact toughness of the type II HH alloy at elevated temperatures are shown in Fig. 9(a). The HH alloy (type I or II) is seldom used for carburizing applications because of embrittlement from carbon absorption. High silicon content (over 1.5%) will fortify the alloy against carburization under mild conditions, but will promote ferrite formation and possible σ embrittlement.

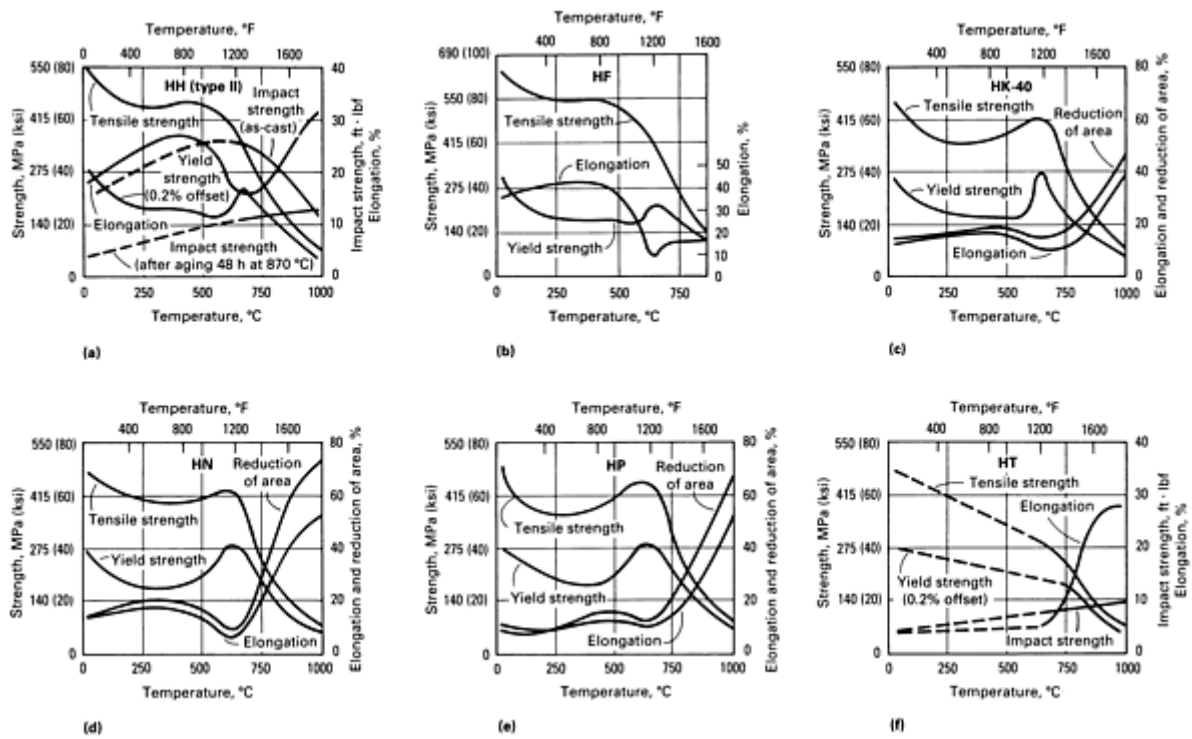

Fig. 9 Effect of short-term elevated-temperature exposure on the tensile properties of wholly austenitic (type II) HH cast steel (a) and of five other heat-resistant cast steels: (b) HF cast steel, (c) HK-40 cast steel, (d) HN cast steel, (e) HP cast steel, and (f) HT cast steel. Long-term elevated-temperature exposure reduces the strengthening effects between 500 to 750 °C (900 to 1400 °F) in (c), (d), and (e). Tensile properties of alloy HT in (f) include extrapolated data (dotted lines) below 750 °C but should be similar to alloy HN in terms of yield and tensile strengths. Source: Ref 9

For the wholly austenitic (type II) HH alloy, composition balance is critical in achieving the desired austenitic microstructure (see "Composition and Microstructure" in this article). An imbalance of higher levels of ferrite-promoting elements compared to levels of austenite-promoting elements may result in substantial amounts of ferrite which improves ductility, but decreases strength at high temperatures. If a balance is maintained between ferrite-promoting elements (such as chromium and silicon) and austenite-promoting elements (such as nickel, carbon, and nitrogen), the desired austenitic structure can be obtained. In commercial HH alloy castings, with the usual carbon, nitrogen, manganese, and silicon contents, the ratio of chromium to nickel necessary for a stable austenitic structure is expressed by the inequality:

$$\frac{\%Cr - 16(\%C)}{\%Ni} < 1.7 \quad (\text{Eq 3})$$

Silicon and molybdenum have definite effects on the formation of σ phase. A silicon content in excess of 1% is equivalent to a chromium content three times as great, and any molybdenum content is equivalent to a chromium content four times as great.

Before HH alloy is selected as a material for heat-resistant castings, it is advisable to consider the relationship between chemical composition and operating-temperature range. For castings that are to be exposed continuously at temperatures appreciably above 870 °C (1600 °F), there is little danger of severe embrittlement from either the precipitation of carbide or the formation of σ phase, and composition should be 0.50% C (max) (0.35 to 0.40% preferred), 10 to 12% Ni, and 24 to 27% Cr. On the other hand, castings to be used at temperatures from 650 to 870 °C (1200 to 1600 °F) should have compositions of 0.40% C (max), 11 to 14% Ni, and 23 to 27% Cr. For applications involving either of these temperature ranges, that is, 650 to 870 °C (1200 to 1600 °F), or appreciably above 870 °C (1600 °F), composition should be balanced to provide an austenitic structure. For service from 650 to 870 °C (1200 to 1600 °F), for example, a combination of 11% Ni and 27% Cr is likely to produce σ phase and its associated embrittlement, which occurs most rapidly around 870 °C (1600 °F). It is preferable, therefore, to avoid using the maximum chromium content with the minimum nickel content.

Short-time tensile testing of fully austenitic HH alloys shows that tensile strength and elongation depend on carbon and nitrogen contents. For maximum creep strength, HH alloy should be fully austenitic in structure (Fig. 10). In design of load-carrying castings, data concerning creep stresses should be used with an understanding of the limitations of such data. An extrapolated limiting creep stress for 1% elongation in 10,000 h cannot necessarily be sustained for that length of time without structural damage. Stress-rupture testing is a valuable adjunct to creep testing and a useful aid in selecting section sizes to obtain appropriate levels of design stress.

Fig. 10 Creep strength of heat-resistant alloy castings (HT curve is included in both graphs for ease of comparison). Source: Ref 10

Because HH alloys of wholly austenitic structure have greater strength at high temperatures than partly ferritic alloys of similar composition, measurement of ferrite content is recommended. Although a ratio calculated from Eq 3 that is less than 1.7 indicates wholly austenitic material, ratios greater than 1.7 do not constitute quantitative indications of ferrite content. It is possible, however, to measure ferrite content by magnetic analysis after quenching from about 1100 °C (2000 °F). The magnetic permeability of HH alloys increases with ferrite content. This measurement of magnetic permeability, preferably after holding 24 h at 1100 °C (2000 °F) and then quenching in water, can be related to creep strength, which also depends on structure.

HH alloys are often evaluated by measuring percentage elongation in room-temperature tension testing of specimens that have been held 24 h at 760 °C (1400 °F). Such a test may be misleading because there is a natural tendency for engineers to favor compositions that exhibit the greatest elongation after this particular heat treatment. High ductility values are often measured for alloys that have low creep resistance, but, conversely, low ductility values do not necessarily connote high creep resistance.

HI alloy (28Cr-15Ni) is similar to HH but contains more nickel and chromium. The higher chromium content makes HI more resistant to oxidation than HH, and the additional nickel serves to maintain good strength at high temperatures. Exhibiting adequate strength, ductility, and corrosion resistance, this alloy has been used extensively for retorts operating with an internal vacuum at a continuous temperature of 1175 °C (2150 °F). It has an essentially austenitic structure that contains carbides and that, depending on the exact composition balance, may or may not contain small amounts of ferrite. Service at 760 to 870 °C (1400 to 1600 °F) results in precipitation of finely dispersed carbides, which increases strength and decreases ductility at room temperature. At service temperatures above 1100 °C (2000 °F), however, carbides remain in solution, and room-temperature ductility is not impaired.

HY alloy (26Cr-20Ni) is somewhat similar to wholly austenitic HH alloy in general characteristics and mechanical properties. Although less resistant to oxidizing gases than HC, HE or HI (Table 12), HK alloy contains enough chromium to ensure good resistance to corrosion by hot gases, including sulfur-bearing gases, under both oxidizing and reducing conditions. The high nickel content of this alloy helps make it one of the strongest heat-resistant casting alloys at temperatures above 1040 °C (1900 °F). Accordingly, HK alloy castings are widely used for stressed parts in structural applications at temperatures up to 1150 °C (2100 °F). As normally produced, HK is a stable austenitic alloy over its entire range of service temperatures. The as-cast microstructure consists of an austenitic matrix containing relatively large carbides in the forms of either scattered islands or networks. After the alloy has been exposed to service temperature, fine, granular carbides precipitate within the grains of austenite and, if the temperature is high enough, undergo subsequent agglomeration. These fine, dispersed carbides contribute to creep strength. A lamellar constituent that resembles pearlite, but that is presumed to be carbide or carbonitride platelets in austenite, is also frequently observed in HK alloy.

Table 12 Approximate rates of corrosion for ACI heat-resistant casting alloys in air and in flue gas

Alloy	Oxidation rate in air, mm/yr			Corrosion rate, mm/yr, at 980 °C (1800 °F) in flue gas with sulfur content of:			
	870 °C (1600 °F)	980 °C (1800 °F)	1090 °C (2000 °F)	0.12 g/m ³		2.3 g/m ³

Source: Ref 11

Unbalanced compositions are possible within the standard composition range for HK alloy, and hence some ferrite may be present in the austenitic matrix. Ferrite will transform to brittle σ phase if the alloy is held for more than a short time at about 815 °C (1500 °F), with consequent embrittlement upon cooling to room temperature. Direct transformation of austenite to σ phase can occur in HK alloy in the range of 760 to 870 °C (1400 to 1600 °F), particularly at lower carbon levels (0.20 to 0.30%). The presence of σ phase can cause considerable scatter in property values at intermediate temperatures.

The minimum creep rate and average rupture life of HK are strongly influenced by variations in carbon content. Under the same conditions of temperature and load, alloys with higher carbon content have lower creep rates and longer lives than lower-carbon compositions. Room-temperature properties after aging at elevated temperatures are affected also: The higher the carbon, the lower the residual ductility. For these reason, three grades of HK alloys with carbon ranges narrower than the standard HK alloy in Table 2 are recognized: HK-30, HK-40, and HK-50. In these designations, the number indicates the midpoint of a 0.10% C range. HK-40 (Table 2) is widely used for high-temperature processing equipment in the petroleum and petro-chemical industries.

Figure 9(c) shows the effect of short-term temperature exposure on an HK-40 alloy. Figure 11 indicates the statistical spread in room-temperature mechanical properties obtained for an HK alloy. These data were obtained in a single foundry and are based on 183 heats of the same alloy.

Fig. 11 Statistical spread in mechanical properties of HK alloy. Data are for 183 heats of HK alloy produced in a single foundry. Tests were performed at room temperature on as-cast material.

HL alloy (30Cr-20Ni) is similar to HK; its higher chromium content gives it greater resistance to corrosion by hot gases, particularly those containing appreciable amounts of sulfur. Because essentially equivalent high-temperature strength can be obtained with either HK or HL, the superior corrosion resistance of HL makes it especially useful for service in which excessive scaling must be avoided. The as-cast and aged microstructures of HL alloy, as well as its physical properties and fabricating characteristics, are similar to those of HK.

Iron-Nickel-Chromium Heat-Resistant Castings

Iron-nickel-chromium alloys generally have more stable structures than those of iron-base alloys in which chromium is the predominant alloying element. There is no evidence of an embrittling phase change in iron-nickel-chromium alloys that would impair their ability to withstand prolonged service at elevated temperature. Experimental data indicate that composition limits are not critical; therefore, the production of castings from these alloys does not require the close composition control necessary for making castings from iron-chromium-nickel alloys.

The following general observations should be considered in the selection of iron-nickel-chromium alloys:

- As nickel content is increased, the ability of the alloy to absorb carbon from a carburizing atmosphere decreases
- As nickel content is increased, tensile strength at elevated temperatures decreases somewhat, but resistance to thermal shock and thermal fatigue increases
- As chromium content is increased, resistance to oxidation and to corrosion in chemical environments increases
- As carbon content is increased, tensile strength at elevated temperatures increases
- As silicon content is increased, tensile strength at elevated temperatures decreases, but resistance to carburization increases somewhat

HN alloy (25Ni-20Cr) contains enough chromium for good high-temperature corrosion resistance. HN has mechanical properties somewhat similar to those of the much more widely used HT alloy, but has better ductility (see Fig. 9d and 9f for a comparison of HN and HT tensile properties above 750 °C, or 1400 °F). It is used for highly stressed components in the temperature range of 980 to 1100 °C (1800 to 2000 °F). In several specialized applications (notably, brazing fixtures), it has given satisfactory service at temperatures from 1100 to 1150 °C (2000 to 2100 °F). HN alloy is austenitic at all temperatures: Its composition limits lie well within the stable austenite field. In the as-cast condition it contains carbide areas, and additional fine carbides precipitate with aging. HN is not susceptible to σ phase formation, and increases in its carbon content are not especially detrimental to ductility.

HP, HT, HU, HW, and HX alloys make up about one-third of the total production of heat-resistant alloy castings. When used for fixtures and trays for heat treating furnaces, which are subjected to rapid heating and cooling, these five high-nickel alloys have exhibited excellent service life. Because these compositions are not as readily carburized as iron-chromium-nickel alloys, they are used extensively for parts of carburizing furnaces. Because they form an adherent scale that does not flake off, castings of these alloys are also used in enameling applications in which loose scale would be detrimental.

Four of these high-nickel alloys (HT, HU, HW, and HX) also exhibit good corrosion resistance with molten salts and metal. They have excellent corrosion resistance to tempering and to cyaniding salts and fair resistance to neutral salts, with proper control. With molten metal, these alloy exhibit excellent resistance to molten lead, good resistance to molten tin to 345 °C (650 °F), and good resistance to molten cadmium to 410 °C (775 °F). The alloys have poor resistance to antimony, babbitt, soft solder, and similar metal. In many respects, there are no sharp lines of demarcation among the HP, HT, HU, HW, and HX alloys with respect to service applications.

HP alloy (35Ni-26Cr) is related to HN and HT alloys, but is higher in alloy content. It contains the same amount of chromium but more nickel than HK, and the same amount of nickel but more chromium than HT. This combination of elements makes HP resistant to both oxidizing and carburizing atmospheres at high temperatures. It has creep-rupture properties that are comparable to, or better than, those of HK-40 and HN alloys (Fig. 12).

(a)

(b)

Fig. 12 Stress-rupture properties of several heat-resistant alloy castings. (a) 10,000 h rupture stress. (b) 100,000 h rupture stress. Source: Ref 10

HP alloy is austenitic at all temperatures, and is not susceptible to σ -phase formation. Its microstructure consists of massive primary carbides in an austenitic matrix; in addition, fine secondary carbides are precipitated within the austenite grains upon exposure to elevated temperatures. This precipitation of carbides is responsible for the strengthening between 500 and 750 °C (900 and 1400 °F) in Fig.(e) 9. This strengthening, which is reduced after long-term exposure at high temperatures, also occurs for the cast stainless steels shown in Fig. (c) 9 and (d) 9.

HT alloy (35Ni-17Cr) contains nearly equal amounts of iron and alloying elements. Its high nickel content enables it to resist the thermal shock of rapid heating and cooling. In addition, HT is resistant to high-temperature oxidation and carburization and has good strength at the temperatures ordinarily used for heat treating steel. Except in high-sulfur gases, and provided that limiting creep-stress values are not exceeded, it performs satisfactorily in oxidizing atmospheres at temperatures up to 1150 °C (2100 °F) and in reducing atmospheres at temperatures up to 1100 °C (2000 °F).

HT alloy is widely used for highly stressed parts in general heat-resistant applications. It has an austenitic structure containing carbides in amounts that vary with carbon content and thermal history. In the as-cast condition, it has large carbide areas at interdendritic boundaries; but fine carbides precipitate within the grains after exposure to service temperature, causing a decrease in room-temperature ductility. Increases in carbon content may decrease the high-temperature ductility of the alloy. A silicon content above about 1.6% provides additional protection against carburization, but at some sacrifice in elevated-temperature strength. HT can be made still more resistant to thermal shock by the addition of up to 2% niobium.

HU alloy (39Ni-18Cr) is similar to HT, but its higher chromium and nickel contents give it greater resistance to corrosion by either oxidizing or reducing hot gases, including those that contain sulfur in amounts up to 2.3 g/m³ (see Table 12). Its high-temperature strength and resistance to carburization are essentially the same as those of HT and thus its superior corrosion resistance makes it especially well suited for severe service involving high stress and/or rapid thermal cycling, in combination with an aggressive environment.

HW alloy (60Ni-12Cr) is especially well suited for applications in which wide and/or rapid fluctuations in temperature are encountered. In addition, HW exhibits excellent resistance to carburization and high-temperature oxidation. HW alloy has good strength at steel-treating temperatures, although it is not as strong as HT. HW performs satisfactorily at temperatures up to about 1120 °C (2050 °F) in strongly oxidizing atmospheres and up to 1040 °C (1900 °F) in oxidizing or reducing products of combustion, provided that sulfur is not present in the gas. The generally adherent nature of its oxide scale makes HW suitable for enameling furnace service, where even small flakes of dislodged scale could ruin the work in process.

HW alloy is widely used for intricate heat-treating fixtures that are quenched with the load and for many other applications (such as furnace retorts and muffles) that involve thermal shock, steep temperature gradients, and high stresses. Its structure is austenitic and contains carbides in amounts that vary with carbon content and thermal history. In the as-cast condition, the microstructure consists of a continuous interdendritic network of elongated eutectic carbides. Upon prolonged exposure at service temperatures, the austenitic matrix becomes uniformly peppered with small carbide particles except in the immediate vicinity of eutectic carbides. This change in structure is accompanied by an increase in room-temperature strength, but there is no change in ductility.

HX alloy (66Ni-17Cr) is similar to HW, but contains more nickel and chromium. Its higher chromium content gives it substantially better resistance to corrosion by hot gases (even sulfur-bearing gases), which permits it to be used in severe service applications at temperatures up to 1150 °C (2100 °F). However, it has been reported that HX alloy decarburized rapidly at temperatures from 1100 to 1150 °C (2000 to 2100 °F). High-temperatures strength (Table 11), resistance to thermal fatigue, and resistance to carburization are essentially the same as for HW; hence HX is suitable for the same general applications in which corrosion must be minimized. The as-cast and aged microstructure of HX, as well as its mechanical properties and fabricating characteristics, are similar to those of HW.

Properties of Heat-Resistant Alloys

Elevated-Temperature Tensile Properties. The short-term elevated-temperature test, in which a standard tension test bar is heated to a designated uniform temperature and then strained to fracture at a standardized rate, identifies the stress due to a short-term overload that will cause fracture in uniaxial loading. The manner in which the values of tensile strength and ductility change with increasing temperature is shown in Fig. 9 for selected alloys. Representative tensile properties at temperatures between 760 and 980 °C (1400 and 1800 °F) are given in Table 11 for several heat-resistant cast steel grades.

Creep and Stress-Rupture Properties. Creep is defined as the time-dependent strain that occurs under load at elevated temperature and is operative in most applications of heat-resistant high-alloy castings at the normal service temperatures. In time, creep may lead to excessive deformation and even fracture at stress considerably below those determined in room-temperature and elevated-temperature short-term tension tests.

When the rate or degree of deformation is the limiting factor, the design stress is based on the minimum creep rate and design life after allowing for initial transient creep. The stress that produces a specified minimum creep rate of an alloy or a specified amount of creep deformation in a given time (for example, 1% total creep in 100,000 h) is referred to as the limiting creep strength, or limiting stress. Table 9 lists the creep strength of various H-type castings at specific temperatures. Figure 10 shows creep rates as a function of temperature.

Stress-rupture testing is a valuable adjunct to creep testing and is used to select the section sizes necessary to prevent creep rupture of a component. Figure 12 compares the creep-rupture strength of various H-type steels castings at 10,000 and 100,000 h. It should be recognized that long-term creep and stress-rupture values (for example, 100,000 h) are often extrapolated from shorter-term tests. Whether these property values are extrapolated or determined directly often has little bearing on the operating life of high-temperatures parts. The actual material behavior is often difficult to predict accurately because of the complexity of the service stresses relative to the idealized, uniaxial loading conditions in the standardized tests and because of the attenuating factors such as cyclic loading, temperature fluctuations, and metal loss from corrosion. The designer should anticipate the synergistic effects of these variables.

Thermal fatigue failure involves cracking caused by heating and cooling cycles. Very little experimental thermal fatigue information is available on which to base a comparison of the various alloys, and no standard test as yet has been adopted. Field experience indicates that resistance to thermal fatigue is usually improved with an increase in nickel content. Niobium-modified alloys have been employed successfully when a high degree of thermal fatigue resistance is desired such as in reformer outlet headers.

Thermal Shock Resistance. Thermal shock failure may occur as a result of a single, rapid temperature change or as a result of rapid cyclic temperature changes, which induce stress that are high enough to cause failure. Thermal shock resistance is influenced by the coefficient of thermal expansion and the thermal conductivity of materials. Increases in the thermal expansion coefficient or decreases in thermal conductivity reduce the resistance against thermal shock. Table 13 lists the thermal conductivities and expansion coefficients for heat-resistant castings at various temperatures. The HA, HC, and HD alloys, because of their predominately ferritic microstructure, have the lowest thermal expansion coefficients and the highest thermal conductivities.

Table 13 Thermal conductivity and mean coefficient of linear thermal expansion of ACI heat-resistant cast steels at various temperatures

Alloy	Mean coefficient of linear thermal expansion for a temperature change				Thermal conductivity, W/m · K, at:		
	From 21 to 540 °C (700 to 1000 °F)		From 21 to 1090 °C (70 to 2000 °F)		100 °C (212 °F)	540 °C (1000 °F)	1090 °C (2000 °F)

Resistance to Hot-Gas Corrosion. The atmospheres most commonly encountered by heat-resistant cast steel are air, flue gases, and process gases; such gases may be either oxidizing or reducing and may be sulfidizing or carburizing if sulfur or carbon is present. The corrosion of heat-resistant alloys by the environment at elevated temperatures varies significantly with alloy type, temperature, velocity, and the nature of the specific environment to which the part is exposed. Table 14 presents a general ranking of the standard cast, heat-resistant grades in various environments at 980 °C (1800 °F). Corrosion rates at other temperatures are given in Table 12.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Manufacturing Characteristics

Foundry practices for cast high-alloy steels for corrosion resistance or heat resistance are essentially the same as those used for cast plain carbon steels. Details on melting practice, metal treatment, and foundry practices, including gating, risering, and cleaning of castings, are available in *Casting*, Volume 15 of *ASM Handbook* (formerly 9th Edition *Metals Handbook*).

Iron-base alloys can be cast from heats melted in electric arc furnaces that have either acid or basic linings. When melting is done in acid-lined furnaces, however, chromium losses are high and silicon content is difficult to control, and thus acid-lined furnaces are seldom used. Alloys that contain appreciable amounts of aluminum, titanium, or other reactive metals are melted by induction or electron beam processes under vacuum or a protective atmosphere prior to casting.

Welding. As the alloy content of steel castings is increased to produce a fully austenitic structure, welding without cracking becomes more difficult. The fully austenitic low-carbon grades tend to form microfissures adjacent to the weld. This tendency toward microfissuring increases as nickel and silicon contents increase and carbon content decreases. Microfissuring is most evident in coarse-grain alloys with a carbon content of approximately 0.10 to 0.20% and a nickel content exceeding 13%. The microfissuring is reduced by an extremely low sulfur content. In welding these grades, low interpass temperatures, low heat inputs, and peening of the weld to relieve mechanical stresses are all effective. If strength is not a great factor, an initial weld deposit or "buttering of the weld" is also occasionally used.

Welding of corrosion-resistant steel castings can be done by shielded metal arc welding, gas tungsten arc welding, gas metal arc welding, and electroslag (submerged arc) welding. Austenitic castings are normally welded without preheat, and are solution annealed after welding. Martensitic castings require preheating to avoid cracking during welding and are given an appropriate postweld heat treatment. Specific conditions for welding specific alloys are listed in Table 15. When welds are properly made, tensile and yield strengths of the welded joint are similar to those of the unwelded castings (Table 8). Elongation is generally lower for specimens taken perpendicular to the weld bead.

Table 15 Welding conditions for corrosion-resistant steel castings

ACI designation	Type of electrodes used ^(a)	Preheat		Postweld heat treatment
		°C	°F	
CA-6NM	Same composition	100-150	212-300	590-620 °C (1100-1150 °F)

CA-15	410	200-315	400-600	610-760 °C (1125-1400 °F), air cool
CA-40	410 or 420	200-315	400-600	610-760 °C (1125-1400 °F), air cool
CB-7Cu	Same composition or 308	Not required		480-590 °C (900-1100 °F), air cool
CB-30	442	315-425	600-800	790 °C (1450 °F) min, air cool
CC-50	446	200-700	400-1300	900 °C (1650 °F), air cool
CD-4MCu	Same composition	Not required		Heat to 1120 °C (2050 °F), cool to 1040 °C (1900 °F), quench
CE-30	312	Not required		Quench from 1090-1120 °C (2000-2050 °F)
CF-3	308L	Not required		Usually unnecessary
CF-8	308	Not required		Quench from 1040-1120 °C (1900-2050 °F)
CF-8C	347	Not required		Usually unnecessary
CF-3M	316L	Not required		Usually unnecessary
CF-8M	316	Not required		Quench from 1070-1150 °C (1950-2100 °F)
CF-12M	316	Not required		Quench from 1070-1150 °C (1950-2100 °F)
CF-16F	308 or 308L	Not required		Quench from 1090-1150 °C (2000-2100 °F)
CF-20	308	Not required		Quench from 1090-1150 °C (2000-2100 °F)
CG-8M	317	Not required		Quench from 1040-1120 °C (1900-2050 °F)
CH-20	309	Not required		Quench from 1090-1150 °C (2000-2100 °F)
CK-20	310	Not required		Quench from 1090-1180 °C (2000-2150 °F)
CN-7M	320	200	400	Quench from 1120 °C (2050 °F)

Note: Metal arc, inert-gas arc, and electroslag welding methods can be used. Suggested electrical settings and electrode sizes for various section thicknesses are:

Section thickness, mm (in.)	Electrode diameter, mm (in.)	Current, A	Maximum arc voltage, V
3.2-6.4 ($\frac{1}{8}$ - $\frac{1}{4}$)	2.4 ($\frac{3}{32}$)	45-70	24
3.2-6.4 ($\frac{1}{8}$ - $\frac{1}{4}$)	3.2 ($\frac{1}{8}$)	70-105	25
3.2-6.4 ($\frac{1}{8}$ - $\frac{1}{4}$)	4.0 ($\frac{5}{32}$)	100-140	25
6.4-13 ($\frac{1}{4}$ - $\frac{1}{2}$)	4.8 ($\frac{3}{16}$)	130-180	26
$\frac{1}{4}$ - 13 ($\frac{1}{8}$)	6.4 ($\frac{3}{32}$)	210-290	27

(a) Lime-coated electrodes are recommended.

Most of the corrosion-resistant cast steels, such as the CF-8 or CF-8M grade, are readily weldable, especially if their microstructures contain small percentages of δ -ferrite. Because stainless steels can become sensitized and lose their corrosion resistance if subjected to temperatures above 425 °C (800 °F), great care must be taken in welding to make certain that the casting or fabricated component is not heated excessively. For this reason, many stainless steels are almost never preheated. In many cases, the weld is cooled with a water spray between passes to reduce the interpass temperature to 150 °C (300 °F) or below.

Any welding performed on the corrosion-resistant grades will affect the corrosion resistance of the casting, but for many services the castings will perform satisfactorily in the as-welded condition. Where extremely corrosive conditions exist or where SCC may be a problem, complete reheat treatment may be required after welding. Heating the casting above 1065 °C (1950 °F) and then cooling it rapidly redissolves the carbides precipitated during the welding operation and restores corrosion resistance.

When maximum corrosion resistance is desired and postweld heat treatment (solution annealing) cannot be performed, alloying elements can be added to form stable carbides. Although niobium and titanium both form stable carbides, titanium is readily oxidized during the casting operation and therefore is seldom used. The niobium-stabilized grade CF-8C is the most commonly used cast grade. The stability of the niobium carbides prevents the formation of chromium carbides and the consequent chromium depletion of the base metal. This grade may therefore be welded without postweld heat treatment. Another approach to take when postweld heat treatment is undesirable or impossible is to keep the carbon content below 0.03%, as in the CF-3 and CF-3M grades. At this low carbon level, the depletion of the chromium due to carbide precipitation is so slight that the corrosion resistance of the grade is unaffected by the welding operation.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Galling

Stainless steel castings are susceptible to galling and seizing when dry surfaces slide or chafe against each other. However, the surfaces of the castings can be nitrided so that they are hard and wear resistant. Tensile properties are not impaired. Nitriding reduces resistance to corrosion by concentrated nitric or mixed acids.

Parts such as gate disks for gate valves are usually furnished in the solution-treated condition, but may be nitrided to reduce susceptibility to seizing in service. Similar results are obtained by hardfacing with cobalt-chromium-tungsten alloys.

Cast Stainless Steels

Revised by Malcolm Blair, Steel Founders' Society of America

Magnetic Properties

The magnetic properties of high-alloy castings depend on microstructure. The straight chromium types are ferritic and ferromagnetic. All other grades are mainly austenitic, with or without minor amounts of ferrite, and are either weakly magnetic or wholly nonmagnetic.

Cast nonmagnetic parts for applications in radar and in minesweepers require close control of ferrite content. Thicker sections have higher permeability than thinner sections. Therefore, to ensure low magnetic permeability in all areas of a casting, magnetic permeability checks should be made on the thicker sections.

Introduction

STAINLESS STEELS are widely used at elevated temperatures when carbon and low-alloy steels do not provide adequate corrosion resistance and/or sufficient strength at these temperatures. Carbon and low-alloy steels are generally more economical than stainless steels and are often used in applications with temperatures below about 370 °C (700 °F). Several low-alloy steels with moderate chromium contents (between 1 and 10%) and improved high-temperature strength are also widely used at elevated temperatures above 370 °C (700 °F). These steels include the creep-resistant chromium-molybdenum ferritic steels discussed in the article "Elevated-Temperature Properties of Ferritic Steels" in this Volume. Carbon steels may even be suitable for temperatures above 370 °C (700 °F), if high strength and oxidation are not concerns.

This article deals with the wrought stainless steels used for high-temperature applications (see the article "Cast Stainless Steels" in this Volume for the elevated-temperature properties of cast stainless steels). Corrosion resistance is often the first criterion used to select stainless steel for a particular application. However, strength is also a significant factor in a majority of elevated-temperature applications and may even be the key factor governing the choice of a stainless steel. The stainless steels used in applications in which high-temperature strength is important are sometimes referred to as heat-resistant steels.

Table 1 gives some typical compositions of wrought heat-resistant stainless steels, which are grouped into ferritic, martensitic, austenitic, and precipitation-hardening grades. Of these steels, the austenitic grades offer the highest strength at high temperatures (Fig. 1). The precipitation-hardening steels have the highest strength at lower temperatures (Fig. 1), but they weaken considerably at temperatures above about 425 °C (800 °F).

Elevated-Temperature Properties of Stainless Steels

Production of Steel

In recent years, the melting and refining of wrought heat-resistant alloys have become more and more sophisticated. Traditionally, special melting techniques have been applied to high-strength, high temperature resistant alloys, which often contain large amounts of reactive elements. However, even for low-alloy steels and other lower-strength materials, innovations in melting have steadily increased as melting and casting techniques have been optimized.

Low-alloy steels are generally melted in electric arc furnaces or in the basic oxygen furnace. Primary melting may be followed by a further refining procedure such as ladle treatments, vacuum arc remelting (VAR), or electroslag remelting (ESR). An ingot or billet product from the electric furnace is used as an electrode in these remelting operations. Vacuum degassing may also be used to remove gases, particularly hydrogen. These alloys may be cast directly into ingots or, in some cases, may be continuously cast. The VAR and ESR steel have fewer segregations and a finer grain size.

Ferritic stainless steels are electric furnace melted; melting is followed by argon-oxygen deoxidation (AOD) for controlled oxidation of impurities such as sulfur and carbon (when used for reducing carbon, the process is often termed argon-oxygen decarburization). Because nitrogen is less expensive, it is often used to replace most of the argon in this process; nitrogen levels in stainless steels are higher today than 20 years ago because of its use in the AOD process. Basic

open hearth melting is also used occasionally, with successful results. Vacuum induction melting and electron beam hearth refining have been used for melting some grades in order to control interstitial elements.

The austenitic 300 and 200 series stainless steels are usually produced by the AOD process. The old process for making stainless steel required the use of the expensive low-carbon ferrochromium to produce these low-carbon alloys. This is unnecessary with the AOD process, and lower-cost high-carbon ferrochromium can be used. The ultimate product is not only less expensive, but is also of better quality. In the AOD process, the carbon monoxide partial pressure over the bath is lowered with argon and/or nitrogen, thus enhancing the removal of carbon by the carbon-oxygen reaction. One disadvantage is the high consumption of expensive argon, but nitrogen can be used to replace most of the argon.

The yield of forgeable stock per ingot is generally higher with vacuum melting because of increased purity. Yield may be increased 10% or more, depending on the alloy. Alloys used for forged gas turbine rotors are manufactured on a large scale by the consumable-electrode vacuum arc process and the electroslag process. In both methods, arc melting is accomplished directly in a water-cooled crucible. Mechanical properties, especially the transverse ductility of forgings made from these ingots, are higher than in forgings made from conventional ingot poured in iron molds.

Elevated-Temperature Properties of Stainless Steels

Product Forms

Wrought stainless steel alloys are manufactured in all the forms common to the metal industry. A partial list of American Society for Testing and Materials (ASTM) specifications for stainless steels products used at elevated temperatures includes:

- Heat-resisting stainless steel plate, sheet, and strip in ASTM A 240
- Heat-resisting stainless steel bars and shapes in ASTM A 479
- Heat-resisting stainless steel forgings in ASTM A 473
- Stainless steel tube in ASTM A 213, A 249, A 268, A 269, A 511, A 632, A 688, A 771, and A 791
- Stainless steel pipe in ASTM A 312, A 376, A 409, A 430, A 731, A 813, and A 814

These specifications include numerous types and variations of stainless steel compositions besides those listed in Table 1. Table 1 does not list silicon contents, which may vary according to product form. For example, 316 stainless steel forgings (ASTM A 473) and bar (ASTM A 479) have silicon contents of 1.0% max, while 316 stainless steel pipe (ASTM A 312) and pressure vessel plate (ASTM A 240) have silicon contents of 0.75% max.

The elevated-temperature properties of any of these materials are influenced to some extent by the form of the product; these properties depend largely on the specific alloy characteristics, such as oxidation resistance, type of oxide scale, thermal conductivity, and thermal expansion. Time-temperature exposure and the duration and type of loading are also significant factors, as are differences in properties among different product forms.

For alloys that form thin, tenacious scales at elevated temperature, the stress-rupture properties of bar and sheet of the same alloy will be about the same. On the other hand, for alloys that are less resistant to oxidation, rupture values are likely to be significantly lower for sheet than for the same alloy in bar form because of the greater ratio of surface area to volume, which causes greater interaction between the environment and the substrate metal. In the case of oxidation, a fixed depth of oxidation (such as 75 to 125 μm , or 3 to 5 mils) will more drastically affect properties in 1.3 mm (50 mil) sheet than in 6.5 mm (250 mil) bar stock.

The high-temperature strength of the heat-resistant alloys can be increased by such cold-working processes as rolling, swaging or hammering. The increased strength is retained, however, only up to the recrystallization temperature. Figure 2, for example, shows the effect of temperature on the tensile properties of cold-worked 301 stainless steel. In particular, cold-worked products have poor resistance to creep, which generally occurs at temperatures slightly above the recrystallization temperature of the metal. During long-term high-temperature exposure, the benefit of cold working is lost, and stress-rupture strength may even fall below annealed strength.

Elevated-Temperature Properties of Stainless Steels

Mechanical Property Considerations

For service at elevated temperatures, the first property considered is the tensile strength during short-term exposure at elevated temperatures (Fig. 1). For applications involving short-term exposure to temperatures below about 480 °C (900 °F), the short-time tensile properties are usually sufficient in the mechanical design of steel components. For temperatures above 480 °C (900 °F), the design process must include other properties such as creep rate, creep-rupture strength, creep-rupture ductility, and creep-fatigue interaction. Mechanical data of various steels at elevated temperatures are available in the ASTM data series (DS) listed in Table 2.

Table 2 Data sources for the mechanical properties of various steels at elevated temperatures

Steel	Data source	Year
Carbon steel	ASTM DS 11S1	1970
	ASTM STP 503	1972
Carbon-molybdenum steel	ASTM DS 47	1971
$\frac{1}{2}$ Cr- $\frac{1}{2}$ Mo, 1Cr- $\frac{1}{2}$ Mo, $1\frac{1}{4}$ Cr- $\frac{1}{2}$ Mo	ASTM DS 50	1973
$2\frac{1}{4}$ Cr-1Mo steel	ASTM DS 6S2	1971
3 to 9Cr-Mo steel	ASTM DS 58	1975
12 to 27 Cr steel	ASTM DS 59	1980
Types 304, 316, 321, and 347 stainless steels	ASTM DS 5S2	1969
	ORNL 5285	Oct 1977

Various methods, depending on the application, are used to establish the design criteria for using materials at elevated temperatures. One method, for example, develops allowable stresses by multiplying tensile strengths, yield strengths, creep strength, and/or rupture strength with safety factors (Fig. 3). This method is illustrated in Fig. 3, where various safety factors are used to establish allowable stresses for 18-8 austenitic stainless steel at various temperatures. This method does not take into account environmental interactions, aging effects from long-term temperature exposure, or the potential of creep-fatigue interaction. Another design basis is to define maximum allowable temperatures. Table 3, for

example, lists maximum allowable service temperatures of various materials for tube and plate products used in refinery or boiler applications.

Table 3 Suggested maximum temperatures for continuous service based on creep or rupture data

Material	Maximum temperature based on creep rate		Maximum temperature based on rupture	
	°C	°F	°C	°F
Carbon steel	450	850	540	1000
C-0.5Mo steel	510	950	595	1100
2.25Cr-1Mo steel	540	1000	650	1200
Type 304 stainless steel	595	1100	815	1500

Fig. 3 Example of relationships between temperature and high-temperature strengths previously used in the ASME Boiler Code (1974) to establish maximum allowable stresses in tension for type 18-8 austenitic stainless steel. The current code uses two-thirds of the yield strength instead of 62.5% of the yield strength.

Creep and Stress Rupture. Creep is defined as the time-dependent strain that occurs under load at elevated temperature. Creep is operative in most applications when metal temperatures exceed 480 °C (900 °F). In time, creep may lead to excessive deformation and even fracture at stresses considerably below those determined in room-temperature and elevated-temperature short-term tension tests. The designer must usually determine whether the serviceability of the component in question is limited by the rate or the degree of deformation.

When the rate or degree of deformation is the limiting factor, the design stress is based on the minimum creep rate and design life after allowing for initial transient creep. The stress that produces a specified minimum creep rate of an alloy or a specified amount of creep deformation in a given time (for example, 1% total creep in 100,000 h) is referred to as the limiting creep strength or limiting stress. Of the various types of stainless steels, the austenitic types provide the highest limiting creep strength. Figure 4 plots typical creep rates of various austenitic stainless steels. The original data for Fig. 4 were generated on steels with carbon contents greater than 0.04%; the steels were solution annealed at sufficiently high temperatures to meet H grade requirements (see the section "H Grades" in this article). Today, the 300-series stainless steels are usually low carbon, unless an H grade is specified.

Fig. 4 Creep rate curves for several annealed H-grade austenitic stainless steels. (a) 1% creep in 100,000 h. (b) 1% creep in 10,000 h. Source: Ref 1

When fracture is the limiting factor, stress-to-rupture values can be used in design. Typical stress-to-rupture values of various austenitic stainless steels are shown in Fig. 5. The values were generated from steels meeting H grade requirements.

Fig. 5 Stress-rupture curves for several annealed H-grade austenitic stainless steels. (a) Extrapolated data for rupture in 100,000 h. (b) Rupture in 10,000 h. Source: Ref 1

It should be recognized that long-term creep and stress-rupture values (for example, 100,000 h) are often extrapolated from shorter-term tests, which are conducted at high stresses and in which creep is dislocation controlled. Whether these property values are extrapolated or determined directly often has little bearing on the operating life of high-temperature

parts, where operating stresses are lower and where the mechanisms of creep are diffusion controlled. The actual material behavior can also be difficult to predict accurately because of the complexity of the service stresses relative to the idealized, uniaxial loading conditions in the standardized tests and because of attenuating factors such as cyclic loading, temperature fluctuations, and metal loss from corrosion.

Rupture Ductility. While creep strength and rupture strength are given considerable attention as design and failure parameters, rupture ductility is an important mechanical property when stress concentrations and localized defects such as notches are a factor in design. Rupture ductility, which varies inversely with creep and rupture strength, influences the growth of cracks or defects and thus affects notch sensitivity. This general effect of rupture ductility on rupture strength is shown conceptually in Fig. 6. When smooth parts are tested, the rupture strength is higher for the steel with lower ductility (steel A). However, when a notch is introduced, the rupture strength of steel A plummets; the rupture strength of steel B, on the other hand, is less notch sensitive because of its higher ductility. It is clear from Fig. 6 that for low-stress, long-term applications, steel B would be preferred to steel A. This is true even though steel B is weaker than steel A, as shown by results of smooth-bar rupture tests.

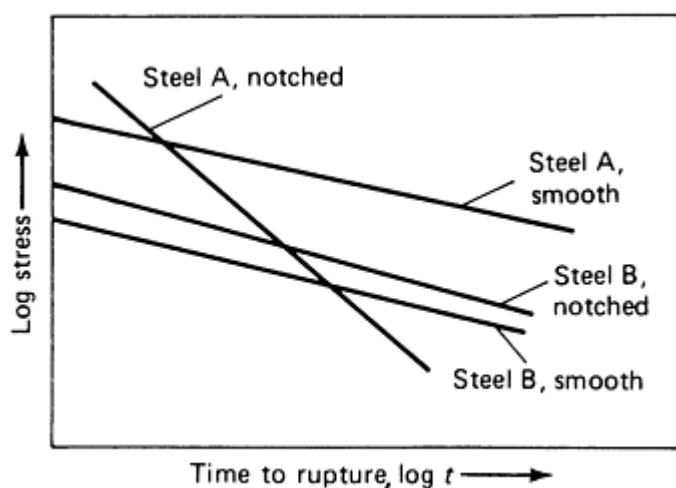

Fig. 6 Notched-bar rupture behavior for a creep-brittle steel (A) and a creep-ductile steel (B)

In many service conditions, the amount of deformation is not critical, and relatively high rupture ductility can be used in design. Under such conditions, with the combined uncertainties of actual stress, temperature, and strength, it may be important that failure not occur without warning and that the metal retain high elongation and reduction in area throughout its service life. In the oil and chemical industries, for instance, many applications of tubing under high pressure require high long-time ductility, so that impending rupture will be evident from the bulging of the tubes.

Values of elongation and reduction in area obtained in rupture tests are used in judging the ability of metal to adjust to stress concentration. The requirements are not well defined and are controversial. Most engineers are reluctant to use alloys with elongations of less than 5%, and this limit is sometimes considerably higher. Low ductility in a rupture test almost always indicates high resistance to the relaxation of stress by creep, and possible sensitivity to stress concentrations. There is also ample evidence that rupture ductility has a major influence on creep-fatigue interaction (see the section below). Large changes in elongation with increasing fracture time usually indicate extensive changes in metallurgical structure or surface corrosion.

Creep-fatigue interaction is a phenomenon that can have a detrimental effect on the performance of metal parts or components operating at elevated temperature. When temperatures are high enough to produce creep strains and when cyclic (that is, fatigue) strains are present, the two can interact with one another. For example, it has been found that creep strains can seriously reduce fatigue life and that fatigue strains can seriously reduce creep life. This effect occurs in both stainless steels and low-alloy or carbon steels when temperatures are in the creep range (see the article "Elevated-Temperature Properties of Ferritic Steels" in this Volume).

Creep-fatigue interaction causes a reduction in fatigue life when either the frequency of the cycling stress is reduced or the cycling waveform has a tensile (and sometimes compressive) hold time (Fig. 7). Early studies (Ref 3, 4, 5, 6, 7, 8) on AISI type 316 stainless steel showed that tensile hold periods in the temperature region from 550 to 625 °C (1020 to 1160 °F) were very damaging, as shown in Fig. 7. Because the strain ranges were fairly high and the hold periods were short, failures were dominated by fatigue. More recent results at lower strain ranges and longer hold periods have revealed that creep-dominated failures also occur in stainless steels (Ref 9, 10, 11). Creep-dominated failures have been observed for tensile hold times up to 16 h at 600 °C (1110 °F) (Ref 9) and in tests at 625 °C (1160 °F) with tensile hold times up to 48 h (Ref 10).

Fig. 7 Effect of tensile hold time on fatigue endurance of type 316 stainless steel. Source: Ref 2

Some investigators have observed a saturation in the detrimental effects of tensile hold periods, that is, a recovery of the endurance occurring at longer hold periods. This has been attributed to microstructural changes leading to increases in ductility. Aging and the concomitant precipitation and growth of large carbides prior to testing have been shown to eliminate creep-fatigue effects altogether in type 316 stainless steel at 650 °C (1200 °F) (Ref 12). Compressive holds have been found to have an effect similar to that in chromium-molybdenum-vanadium steels; that is, they nullified the detrimental effects caused by tensile holds. The effect of slow-fast cycles, in which the strain increased slowly during the tension cycle but increased rapidly during the compression-going cycle, on the endurance of type 304, type 316, and other stainless steels has been investigated (Ref 13, 14, 15, 16). In other tests, low strain rates in the tension cycle were found to reduce endurance. Data on creep-fatigue interaction for various stainless steels are given in the article "Creep-Fatigue Interaction" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Life reduction due to tensile hold has been observed to be related to stress-rupture ductility, leading to heat-to-heat variations (Ref 11, 17). The influence of rupture ductility on the creep fracture component of creep-fatigue interaction is negligible in continuous-cycle and high-frequency or short hold time fatigue tests (where fracture is fatigue dominated). However, as frequency is decreased or as hold time is increased the effect of rupture ductility becomes more pronounced, as illustrated in Fig. 8(b). The hold time effects on the fatigue lives of two rotors are compared in Fig. 8(b) in terms of their rupture-ductility behavior. The fatigue life of the low-ductility rotor steel is much more adversely affected by hold time than that of the high-ductility rotor steel. The rupture ductilities diverge with increasing time to rupture (Fig. 8a), which is correspondingly reflected in the long hold time tests. Endurance data for several ferritic steels and austenitic stainless steels in relation to the range of rupture ductility exhibited by them are presented in Ref 16. The lower the ductility, the lower the creep-fatigue endurance. In addition, long hold periods, small strain ranges, and low ductility favor creep-dominated failures, whereas short hold periods, intermediate strain ranges, and high creep ductility favor creep-fatigue interaction failures.

Fig. 8 Effects of creep-rupture ductility (a) on hold time effects (b) during low-cycle fatigue testing of a 1Cr-molybdenum-vanadium steel at 500 °C (930 °F). N_{f0} = fatigue life with zero hold time. Source: Ref 18

Corrosion Considerations

The corrosion and oxidation resistance of wrought stainless steels is similar to that of cast stainless steels with comparable compositions. However, austenitic cast stainless steels may have a more pronounced duplex (ferrite-in-austenite) structure than wrought austenitic stainless steels. This ferrite-in-austenite stainless steel is beneficial in preventing intergranular stress-corrosion cracking (see the article "Cast Stainless Steels" in this Volume for the general corrosion resistance of stainless steels at elevated temperatures).

Cast and wrought steels with similar composition, heat treatment, and microstructure (as noted above) exhibit about the same corrosion resistance in a given environment. The temperature limits in air for various stainless steels are given in the article "Wrought Stainless Steels" in this Volume. Because oxidation resistance is affected by many factors, including temperature, time, type of service (cyclic or continuous), and atmosphere, selection of material for a specific application should be based on tests that duplicate anticipated conditions as closely as possible. Figure 9 compares the oxidation resistance of type 430, type 446, and several martensitic and austenitic grades in 1000-h continuous exposure to water-saturated air at temperatures from 815 to 1095 °C (1500 to 2000 °F).

Fig. 9 The 1000-h oxidation resistance of selected stainless steels

Sulfur attack is second only to air oxidation in frequency of occurrence in many industries and is likely to be more severe. Figure 10 shows average corrosion rates at high temperatures from sulfur corrosion in a hydrogen-free environment. Figure 11 shows corrosion from hydrogen sulfide. Additional information on corrosion is given in the sections below and in the article "Wrought Stainless Steels" in this Volume.

Elevated-Temperature Properties of Stainless Steels

Ferritic Stainless Steels

The main advantage of ferritic stainless steels for high-temperature use is their good oxidation resistance, which is comparable to that of austenitic grades. Ferritic stainless steels can also be more resistant to liquid metal attack than austenitic stainless steels. They are therefore used for some applications in the lead and copper metal industries.

In view of their lower alloy content and lower cost, ferritic steels should be used in preference to austenitic steels, stress conditions permitting. Ferritic stainless steels can also be more desirable than austenitic steels in applications with thermal cycling because ferritic steels have higher thermal conductivities and lower thermal expansion coefficients than austenitic steels. Ferritic steels may therefore allow reductions in thermal stresses and improved thermal-fatigue resistance.

For the purposes of this article, ferritic stainless steels are classified into two categories:

- Ferritic stainless steels without vanadium (Table 1)
- High-chromium ferritic steels with vanadium (Table 4)

These two categories are described in the next two sections. An important structural characteristic of all ferritic stainless steels is precipitation of alpha prime (α'), a chromium-rich ferrite, when the steel is exposed to temperatures in the range from 370 to 540 °C (700 to 1000 °F). This precipitation results in an increase in hardness and a drastic reduction in room-temperature toughness, which is known as 475 °C (885 °F) embrittlement (see the article "Embrittlement of Steels" in this Volume). This embrittlement occurs in all ferritic grades that have chromium contents above approximately 13%, and its severity increases at higher chromium levels. This characteristic has to be taken into consideration for applications involving exposure to temperatures in the range from 370 to 540 °C (700 to 1000 °F) because subsequent room-temperature ductility will be severely impaired. In the higher-chromium alloys such as 18Cr-2Mo, type 446, 26-1, and 29-4 (Table 1), σ phase is encountered at temperatures above 565 °C (1050 °F). The χ phase will also form in 26-1Ti and 29Cr-4Mo. The high-molybdenum steels such as 29Cr-4Mo will also form a χ phase, which has an embrittling effect similar to that of the σ phase. The χ phase is only formed in high-molybdenum steels. Titanium has little, if any, effect on the formation of χ phase.

Elevated-Temperature Properties of Stainless Steels

Ferritic Stainless Steels Without Vanadium

Many stainless steels of the 400 series (Table 1) have essentially ferritic structures at all temperatures. Types 405, 430, 434 and 446 form a certain amount of austenite when heated to high temperatures. Type 409 may also form some austenite, particularly if the titanium content is relatively low, but the other steels listed are completely ferritic at all temperatures.

The amount of chromium added for corrosion and oxidation resistance varies from 11% in type 409 to 29% in 29Cr-4Mo. Titanium is used to tie up carbon and nitrogen for structure control and resistance to intergranular corrosion. Molybdenum is used to improve corrosion resistance, whereas aluminum and silicon are added for resistance to oxidation.

Tensile and yield strengths of ferritic stainless steels in Table 1 in the annealed condition are shown in Fig. 12. At room temperature, these properties are nearly equivalent to those of austenitic stainless steels. At higher temperatures, however, ferritic steels are much lower in strength. The rupture strength and creep strength of types 430 and 446 are compared with the same properties of various austenitic stainless steels and two nickel-base alloys (Inconel and Incoloy) in Fig. 13. Long-time and short-time high-temperature strengths of ferritic steels are relatively low compared to those of austenitic steels. Data on the cyclic oxidation resistance of ferritic stainless steels in air containing 10% water vapor are presented in Table 5. At 705 and 815 °C (1300 and 1500 °F), all the alloys listed are resistant to oxidation. At 980 °C (1800 °F), the lower-alloy types 409, 430, and 304 exhibit high oxidation. At 1090 °C (2000 °F), alloys 18 SR and Inconel 601 (shown in Table 5) and alloys such as 446 and 310 have adequate oxidation resistance. The cycling oxidation resistance of E-Brite 26-1, type 310, and Incoloy 800 are compared in Fig. 14.

Table 5 Cyclic oxidation resistance of ferritic stainless steels

Specimens were exposed for 100 h in air containing 10% water vapor, cooled to room temperature every 2 h, then reheated to test temperature.

Alloy	Weight change (scale not removed), g/m ² , at:			
	705 °C (1300 °F)	815 °C (1500 °F)	980 °C (1800 °F)	1090 °C (2000 °F)
409	+0.1	+0.8	+1430 ^(a)	-10,000 ^(b)
430	+0.4	+1.3	-1660 ^(c)	-10,000 ^(b)
18 SR	+0.1	+0.3	+2.5	+7.4
304	+0.2	+1.7	-3400	-10,000 ^(d)
309	+0.2	+2.7	-120	-910
201	+0.8	+3.1	+10	-150

Incoloy 800	+0.3	+3.2	+8.6	-560

Type 409, the lowest-alloy stainless steel with a nominal chromium content of 11.0%, is used extensively because of its good fabricating characteristics, including weldability and formability, and its availability. Its best-known high-temperature applications are in automotive exhaust systems; metal temperatures in catalytic converters exceed 540 °C (1000 °F). Type 409 is also used for exhaust ducting and silencers in gas turbines. Type 405 is used in stationary vanes and spacers in steam turbines and in various furnace components. Types 430 and 439 are used for heat exchangers, hot-water tanks, condensers, and furnace parts. Type 18 SR, like type 446, is used in industrial ovens, blowers, exhaust systems, furnace equipment, annealing boxes, kiln liners, and pyrometer tubes.

Elevated-Temperature Properties of Stainless Steels

Heat-Resistant High-Chromium Ferritic Steels

Table 4 lists various precipitation-strengthened high-chromium ferritic steels. These steels contain vanadium and perhaps other carbide formers such as niobium or tungsten to strengthen the steel by precipitation hardening during tempering or elevated-temperature exposure.

Although several steels in Table 4 are not strictly considered stainless steels, the chromium contents are high enough to exhibit corrosion resistance comparable to that of typical stainless steels. Some of these steels, such as the modified 9Cr-1Mo steel, are also substitutes for austenitic steels in boiler tube applications, as described below. The modified 9Cr-1Mo steel, which is designated ASTM grade 91, is specified in ASTM standards for boiler tubes (ASTM A 213), forgings (ASTM A 336), seamless pipe (ASTM A 335), and forged and bored pipe (ASTM A 369). High-chromium ferritic steels are also used for steam turbine rotors and bolting materials.

Historical Background. High-chromium heat-resistant ferritic steels were first developed for use in gas and steam turbine applications. In the early 1940s, a need for improved high-strength, corrosion-resistant materials for gas turbine disks and steam turbine blades, operating at temperatures near 540 °C (1000 °F), led metallurgists in England to increase development work on 12% Cr heat-resistant steels. This research produced two steels (H-46 and FV448 in Table 4) and

other alloy steels in the 1950s with improved creep-rupture strengths. During the same time period, other 12% Cr alloys such as AISI 422 (UNS S42200) and Lapelloy (listed in Table 4) were introduced in the United States; they have been used for steam turbine blades and bolting materials for turbine cylinders. Work in Japan led to the development in 1956 of TAF steel (Table 4), which is twice as strong as H-46 at 650 °C (1200 °F).

Turbine Rotors. The elevated-temperature strength of turbine rotors is a major factor that influences the allowable temperature conditions of turbines.

The heat-resistant high-chromium ferritic steels developed in the 1950s, such as H-46 and AISI 422, have good creep-rupture strengths and are widely used in steam and gas turbines. Also General Electric's rotor steel (Table 4), with improved creep-rupture strength at 570 °C (1060 °F), was developed in the early 1960s for application in supercritical steam power plants.

In the early 1980s, joint research by Kobe Steel and Mitsubishi Heavy Industry produced modified versions of ferritic TAF steel for operation at 620 °C (1150 °F). The new rotor steels, TR1100, TR1150, and TR1200 (Table 4) improve creep-rupture strength substantially over the General Electric rotor steel (which exhibits a marked decrease in creep-rupture strength over extended times). These improved rotor steels are based on chemistry modifications. The carbon and nitrogen contents of TR1100 are lowered to 0.13% and 0.04%, respectively, and the steel contains 1.5% Mo for solid-solution strengthening and stabilization of $M_{23}C_6$ and M_6C carbides. In addition, tests show that tungsten has a stronger high-temperature strengthening effect than molybdenum at elevated temperatures. Based on these data, TR1150 and TR1200 steels are being developed with increased tungsten content within a molybdenum equivalence ($Mo\% + \frac{1}{2}W\%$) range of 1.2 to 1.5% Mo.

The rotor steels, such as TR1100 and TR1150, are expected to be used in applications with steam conditions of 595 °C (1100 °F) and 620 °C (1150 °F), respectively, with a rotor design stress of 120 to 130 MPa (17.5 to 18.8 ksi). The TR1200 rotor steel in development is intended for steam conditions of 34 MPa (4.9 ksi) and 650 °C (1200 °F).

Boiler tubing requires a combination of high-temperature strength, good formability, and weldability. Various types of high-chromium heat-resistant ferritic steels for boiler tubes are listed in Table 4, along with two austenitic stainless steels (AISI 304 and 347) for comparison. In addition, the HT-9 and EM-12 alloys in Table 4 are widely used in Europe for boiler tubing.

The 10Cr-2Mo boiler tube steels with niobium and vanadium additions include the T-1 and T-2 steels in Table 4. These steels contain 0.05% and 0.10% C, respectively; this level of carbon provides high-temperature strength as well as the good formability and weldability required for boiler tubing. A chromium content of 10% provides very good high-temperature corrosion resistance at about 600 °C (1100 °F), and other alloying elements produce a 20 to 30% δ -ferrite content, which improves weldability.

Increasing the molybdenum content enhances solution hardening and strengthening by $M_{23}C_6$ and M_6C carbide precipitation and intermetallic compound (Fe_2Mo) formation. However, molybdenum is fixed at 2% for the best corrosion resistance, formability, toughness, and δ -ferrite content.

Small amounts of vanadium and niobium affect the high-temperature strength of this steel significantly. Although the optimum content of vanadium is 0.25% for a carbon content of 0.2%, the addition of this amount to a 0.05% carbon steel causes only V_4C_3 precipitation. Therefore, a maximum vanadium content of 0.10 to 0.15% is necessary to raise high-temperature strength by the gradual precipitation of various carbides such as $M_{23}C_6$, M_6C and NbC. The vanadium content is fixed at 0.10% for good weldability.

The niobium content must be relatively low (0.02 to 0.05%) in these steels so that NbC can dissolve in the matrix when normalized at 1050 °C (1900 °F). However, at the low end of the range, the complete dissolution of carbides results in grain growth at the normalizing temperature with a reduction in notch toughness; thus, niobium content is fixed at 0.05%.

The 0.05% C in T-1 steel is shared to form carbides in the following manner: 0.02% for V_4C_3 , 0.005% for NbC, and 0.025% for $M_{23}C_6$ and M_6C . In addition, the equation $(V/51) + (Nb/93) < (C/12)$ must be satisfied so that $M_{23}C_6$ and M_6C can precipitate along with V_4C_3 and NbC.

The heat-resistant steel designed in this manner is strengthened by the precipitation of very fine V_4C_3 and NbC during tempering and in the early stages of creep, followed by $M_{23}C_6$ and M_6C precipitation. Figure 15 compares the creep-rupture strength of T-1 at 600 °C (1110 °F) with that of other boiler tube materials.

Fig. 15 Creep-rupture strengths of various boiler tube steels at 600 °C (1110 °F). Source: Ref 21

Modified 9 and 12Cr-Mo Boiler Tube Steels. Further investigation of the effects of molybdenum, vanadium plus niobium, chromium, nickel, and tungsten additions led to the development of modified chromium-molybdenum steels. These steels include the TB9 and TB12 alloys (Table 4) developed in Japan and the vanadium-niobium modified 9Cr-1Mo steel developed by Oak Ridge National Laboratory. The modified 9Cr-1Mo steel, previously covered in Code Case 1943 of the ASME Boiler Code, is now covered in the regular code. For boiler tubes, these steels offer a promising alternative to 2.25Cr-1Mo steel and types 304, 316, 321, and 347 austenitic stainless steels. Figure 16 compares the 100,000-h creep-rupture strengths of these steels as a function of temperature.

Fig. 16 100,000-h creep-rupture strength of various steels used in boiler tubes. TB12 steel has as much as five times the 100,000-h creep-rupture strength of conventional ferritic steels at 600 °C (1110 °F). This allows an increase in boiler tube operating temperature of 120 to 130 °C (215 to 235 °F). Source: Ref 21

Quenched and Tempered Martensitic Stainless Steels

Quenched and tempered martensitic stainless steels are essentially martensitic, and harden when air cooled from the austenitizing temperature. These alloys offer good combinations of mechanical properties, with usable short-time strength up to 590 °C (1100 °F), and relatively good corrosion resistance. The strength levels at temperatures up to 590 °C (1100 °F) that can be attained in these alloys through heat treatment are considerably higher than those attainable in ferritic stainless steels, but the martensitic alloys have inferior corrosion resistance. Also, the martensitic stainless steels are not very tough.

These alloys are normally purchased in the annealed or fully treated (hardened and tempered) condition. They are used in the hardened and tempered condition. For best long-time thermal stability, these alloys should be tempered at a temperature that is 110 to 165 °C (200 to 300 °F) above the expected service temperature.

Properties. Quenched and tempered martensitic stainless steels can be grouped according to increasing strength and heat resistance:

- *Group 1* (lowest strength and heat resistance): types 403, 410, and 416
- *Group 2*: Greek Ascoloy and type 431
- *Group 3*: Moly Ascoloy (Jethete M-152)
- *Group 4* (highest strength and heat resistance): H-46 and type 422

A general comparison of mechanical property data is presented in Fig. 17 for some of these alloys. Data for type 410 are typical of group 1 alloys. Data for Greek Ascoloy are typical of data for type 431. Data for Moly Ascoloy are typical of data for group 3 alloys (the composition of Jethete M-152 is very similar to that of Moly Ascoloy). Although H-46 and type 422 are similar in strength, their compositions are somewhat different; therefore, data are shown for both alloys.

Fig. 17 Comparison of mechanical properties of martensitic stainless steels. Heat treating schedules were as follows. Type 410: 1 h at 980 °C (1800 °F), oil quench; 2 h at 650 °C (1200 °F), air cool. H-46: 1 h at 1150 °C (2100 °F), air cool; 2 h at 650 °C (1200 °F), air cool. Type 422: 1 h at 1040 °C (1900 °F), oil quench; 2 h at 650 °C (1200 °F), air cool. Greek Ascoloy: 1 h at 955 °C (1750 °F), oil quench; then 2 h at 650 °C (1200 °F), air cool. Moly Ascoloy: 30 min at 1050 °C (1925 °F), oil quench; then 2 h at 650 °C (1200 °F) air cool

The short-time tensile and rupture data shown in Fig. 17 were generated in tests of material that had been given austenitizing treatments typical for the specific alloys tested. Because these alloys are normally used at service temperatures near 540 °C (1000 °F), although they may be used up to 590 °C (1100 °F), data are shown for a relatively

high tempering temperature of 650 °C (1200 °F), which results in good thermal stability in these alloys at 540 °C (1000 °F).

It should be noted that the group 1 alloys, of which type 410 is typical, show the lowest values of strength capability as a function of test temperature. Greek Ascoloy is considerably stronger than type 410, with a yield strength (0.2% offset) of 480 MPa (70 ksi) and a tensile strength of 585 MPa (85 ksi) at 540 °C (1000 °F). The tensile strength capabilities of H-46, Moly Ascoloy, and type 422 are fairly similar and are the highest in this group of alloys. Tensile elongation data for all these alloys are similar--from about 20% elongation at 21 °C (70 °F) to about 30% at 650 °C (1200 °F).

Stress-rupture data for alloys typical of each subgroup are compared in Fig. 17 by means of a master stress-rupture plot. It should be noted that the niobium-containing H-46 alloy has the highest stress-rupture capability, with type 422, Moly Ascoloy, and Greek Ascoloy, in that order, having increasingly lower rupture capabilities. Type 410 has a very low stress-rupture capability and is the weakest of all the martensitic stainless alloys being considered. The niobium-containing alloys such as H-46 usually show an advantage in stress-rupture capability (creep resistance) for short testing times (100 to 1000 h) but lose their strength advantage when tested for periods of about 10,000 h or more. The favorable effects of niobium additions on short-time stress-rupture properties are attributed to a finely dispersed precipitation of NbC. The favorable effects tend to diminish as tempering temperature is increased, and a coarsely dispersed precipitate is formed. The effect of tempering in service is shown by the hardness data in Fig. 18 for type 422 and H-46. The H-46 alloy shows a larger hardness drop for extended thermal exposure at a testing temperature of 540 °C (1000 °F) than does type 422.

Fig. 18 Approximate effects of time and stress on tempering of types 422 and H-46. Circles indicate specimens heated to 1150 °C (2100 °F) and rapidly cooled, tempered 2 h at 705 °C (1300 °F), and tested (to fracture) at a temperature of 540 °C (1000 °F) and a stress of 380 MPa (55 ksi). Triangles indicate specimens heated to 980 °C (1800 °F) and rapidly cooled, tempered 2 h at 705 °C, and tested (to fracture) at 540 °C (1000 °F) and 275 MPa (40 ksi). Open symbols represent data taken at the unstressed specimen shoulder; solid symbols represent data taken within the stressed gauge length.

Applications. Quenched and tempered martensitic stainless steels find their greatest application in steam and gas turbines, where they are used in blading at temperatures up to 540 °C (1000 °F). Other uses include steam valves, bolts, and miscellaneous parts requiring corrosion resistance and good strength up to 540 °C (1000 °F).

Type 410 is the basic, general-purpose steel, used for steam valves, pump shafts, bolts, and miscellaneous parts requiring corrosion resistance and moderate strength up to 540 °C (1000 °F). Type 403 is similar to 410, but the chemical composition is adjusted to prevent formation of δ ferrite in heavy sections. It is used extensively for steam turbine rotor blades and gas turbine compressor blades operating at temperatures up to 480 °C (900 °F). For this type of application the steel is tempered at 590 °C (1100 °F) or above, after which embrittlement is negligible in the service temperature range of 370 to 480 °C (700 to 900 °F).

A satisfactory heat treatment for these steels is to austenitize at 950 to 980 °C (1750 to 1800 °F), cool rapidly in air or oil, and temper. Cooling from the hot-rolling temperature and tempering without intermediate austenitizing is sometimes practical but may result in a structure that contains free ferrite, which is detrimental to transverse properties. Warm or cold work after tempering sets up residual stresses that can be relieved by heating to approximately 620 °C (1150 °F).

Stress-versus-time deformation curves for type 410 sheet are given in Fig. 19. These values are useful for special applications where heating rates are high.

Fig. 19 Stress-versus-time deformation curves for type 410 stainless steel sheet, showing effect of time at temperature on total deformation at specific stress levels. Design curves in the chart at left represent a heating rate of 90 °C/s (160 °F/s) to 650 °C (1200 °F). Those at right represent a heating rate of 105 °C/s (190 °F/s) to 815 °C (1500 °F). Room-temperature properties of the sheet used in these tests were: tensile strength, 650 to 695 MPa (94.5 to 101 ksi); yield strength at 0.2% offset, 555 to 565 MPa (80.7 to 82.3 ksi); and 9.6 to 16% elongation in 50 mm (2 in.) after air cooling from the normalizing temperature of 955 °C (1750 °F) (AFTR 6731, Part 4)

Greek Ascoloy, type 431, and type 422 are variants of 410, modified by the addition of such elements as nickel, tungsten, aluminum, molybdenum, and vanadium. Nickel serves a useful purpose by causing the steel to be entirely austenitic at conventional heating temperatures when the carbon and chromium contents are such that a two-phase structure would exist if nickel were absent. The tempering temperature for Greek Ascoloy may be 55 °C (100 °F) or more, higher than that for type 410 for equivalent strength and hardness. Type 422 develops the highest mechanical properties and at 650 °C (1200 °F) has a tensile strength equivalent to that of type 403 at 590 °C (1100 °F). The rupture strength of type 422 at 540 °C (1000 °F) is considerably higher than those of the other steels in this series (Fig. 20).

Fig. 20 Tensile, yield, rupture, and creep strengths for seven ferritic and martensitic stainless steels. Types 430 and 446 were annealed. Type 403 was quenched from 870 °C (1600 °F) and tempered at 620 °C (1150 °F). Type 410 was quenched from 955 °C (1750 °F) and tempered at 590 °C (1100 °F). Type 431 was quenched from 1025 °C (1875 °F) and tempered at 590 °C (1100 °F). Greek Ascoloy was quenched from 955 °C (1750 °F) and tempered at 590 °C (1100 °F). Type 422 was quenched from 1040 °C (1900 °F) and tempered at 590 °C (1100 °F).

Types 430 and 446, which have nominal chromium contents of 16 and 25%, respectively, are not hardenable by conventional quenching and tempering treatments. Nitrogen to 0.25% (max) is added to type 446 for grain refinement. These grades are generally used in the annealed condition, but they can be cold worked to increase strength and decrease ductility. They have greater oxidation resistance than the 12% Cr steels and may be used without excessive scaling to temperatures of 840 °C (1550 °F) for type 430 and 1090 °C (2000 °F) for type 446 (Fig. 9). The rate of oxidation and the character of the scale are affected greatly by variations in the chemical and physical nature of the air and gases in the environment, and tests under actual service conditions are required for meaningful evaluation.

These alloys age harden, with a loss of ductility, when held for prolonged periods at 370 to 540 °C (700 to 1000 °F); this age hardening is due to 885 °F embrittlement. A typical hardness-temperature curve for a 27% Cr alloy was obtained on a temperature gradient bar (Fig. 21). The specimen was heated in a specially designed furnace so that one end only was subjected to a maximum and uniform temperature. The opposite end reached about 95 °C (200 °F), and the area between showed a uniform increase in temperature from the colder end to the hotter end. Thermocouples were inserted through the colder end of the bar to different depths so that temperatures could be measured at specified distances from the hot end.

Fig. 21 Hardness values along a temperature gradient bar of type 446 stainless steel (0.19C-0.73Mn-0.54Si-27.31Cr-0.16Ni-0.15N) after exposure for times indicated

The increase in hardness with time at 475 °C (885 °F) and the effect of the increase in chromium content are shown in Fig. 22. Notch sensitivity is greatly increased by the increase in hardness. The embrittled condition can be alleviated, and the original hardness restored, by heating at 590 °C (1100 °F). This embrittlement is significant only for applications in the range from 425 to 540 °C (800 to 1000 °F).

Fig. 22 Effect of time at 475 °C (885 °F) on age-hardening characteristics of chromium steels containing 12, 17, and 27% Cr

Type 430 is used for heat exchange equipment, condensers, and piping for nitric acid, as well as for furnace parts and retorts operating at temperatures up to 840 °C (1550 °F). It can be stamped, spun, and formed more easily than can type 446.

Type 446 is used for furnace parts, oil burners, heat exchangers, kiln liners, glass molds, and stationary soot blowers in steam boilers. Its elevated-temperature strength is low, which is indicated by the creep and rupture-strength values given in Fig. 13. These plots compare elevated-temperature properties of types 410, 430, and 446 with those of several other materials, including the standard austenitic stainless steels, Incoloy, and Inconel, a nickel-base alloy.

Welding. The primary factor in welding martensitic steels is their hardenability. The heat-affected zones surrounding the weld harden upon cooling, setting up stresses that can give rise to cracking. If the filler metal is similar to the parent metal, the weld itself will also harden upon cooling and become very brittle. These difficulties can be avoided by two precautions:

- Using austenitic filler metal, which will remain ductile and will absorb the stresses set up by hardening in the heat-affected zone
- Preheating the work gradually before welding and postheating after welding to avoid quenching stresses and cracks. Preheating should be carried out at 205 to 315 °C (400 to 600 °F); postheating at 590 to 760 °C (1100 to 1400 °F)

Elevated-Temperature Properties of Stainless Steels

Precipitation-Hardening Martensitic Stainless Steels

The precipitation-hardening (PH) martensitic stainless (maraging) steels fill an important position between the chromium-free 18% Ni maraging steels and the 12% Cr, low-nickel quenched and tempered martensitic stainless alloys. These PH alloys contain 12 to 16% Cr for corrosion resistance and scaling resistance at elevated temperatures and have the highest tensile strengths at temperatures below about 450 °C (850 °F), as shown in Fig. 1.

These alloys are normally purchased in the solution-annealed condition. Depending on the application, they may be used in the annealed condition or in the annealed plus age-hardened condition. In some cases, material will be supplied in an overaged condition to facilitate the forming of parts. The formed parts are then solution annealed following fabrication.

Properties. The maraging alloys listed in Table 1 include Custom 450, 17-4 PH, 15-5 PH, Custom 455, and PH 13-8 Mo. Property data for these alloys are shown in Fig. 23. Data for 15-5 PH are not shown separately because the properties of this alloy are very similar to those of 17-4 PH.

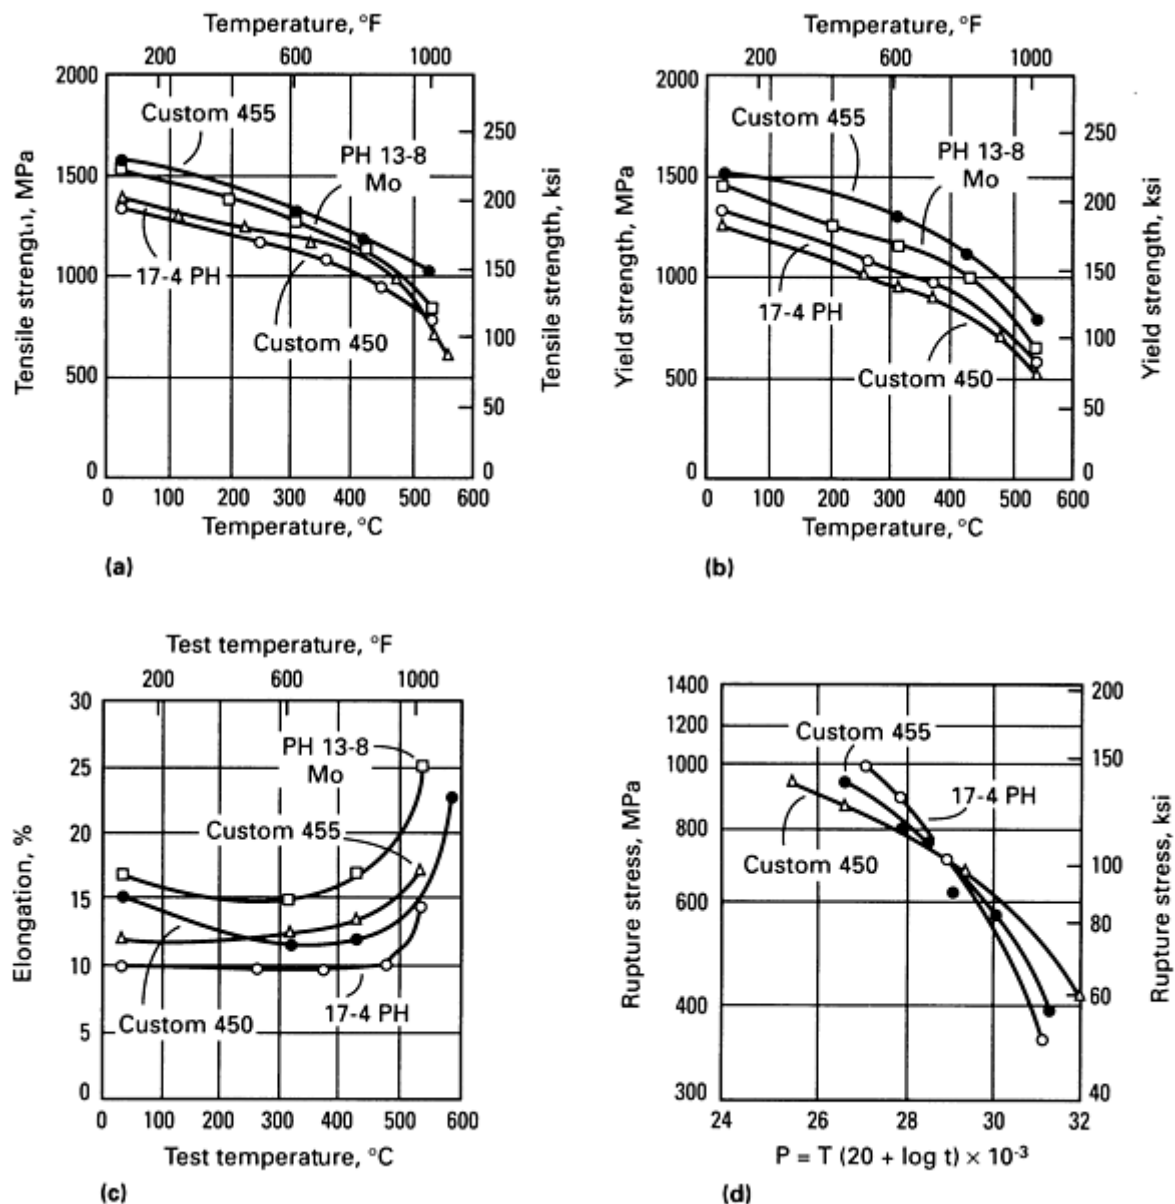

Fig. 23 Comparison of mechanical properties of precipitation-hardening martensitic stainless steels. (a) Tensile strength. (b) Yield strength. (c) Elongation. (d) Rupture strength. Heat treating schedules were as follows. Custom 450: 1 h at 1040 °C (1900 °F), water quench; then 4 h at 480 °C (900 °F), air cool. 17-4 PH: 30 min at 1040 °C (1900 °F), oil quench; then 4 h at 480 °C (900 °F), air cool. Custom 455: 30 min at 815 °C (1500 °F), water quench; then 4 h at 510 °C (950 °F), air cool. PH 13-8 Mo: oil quenched from 925 °C (1700 °F); then 4 h at 540 °C (1000 °F), air cool

Short-time tensile data indicate that Custom 455 and PH 13-8 Mo have higher strengths than Custom 450, 17-4 PH, or 15-5 PH. For all of these alloys, tensile and yield strengths drop rapidly at temperatures above 425 °C (800 °F), and tensile elongation is greater than 10% over the temperature range from ambient to 540 °C (1000 °F).

Stress-rupture data are compared in Fig. 23 by means of a master parameter plot. Data were developed at testing temperatures of 425 and 480 °C (800 and 900 °F) during time periods of 100 and 1000 h. It should be noted that 17-4 PH appears to have better stress-rupture strength at 425 °C (800 °F), whereas Custom 450 is superior in this respect at 480 °C (900 °F). The only stress-rupture data available for Custom 455 appears to indicate that the alloy is intermediate in rupture strength between 17-4 PH and Custom 450.

It is possible to produce a wide variety of useful properties in a given alloy by varying the aging temperature. An example of this can be seen in Fig. 24, where tensile strength, yield strength (0.2% offset), ductility, and impact data are shown for

Custom 450 at three different aging temperatures. Aging at 480 °C (900 °F) can produce significant strengthening at testing temperatures as high as 450 °C (850 °F), but it also results in lower toughness values (as measured by Charpy V-notch testing) than aging at either of the two temperatures.

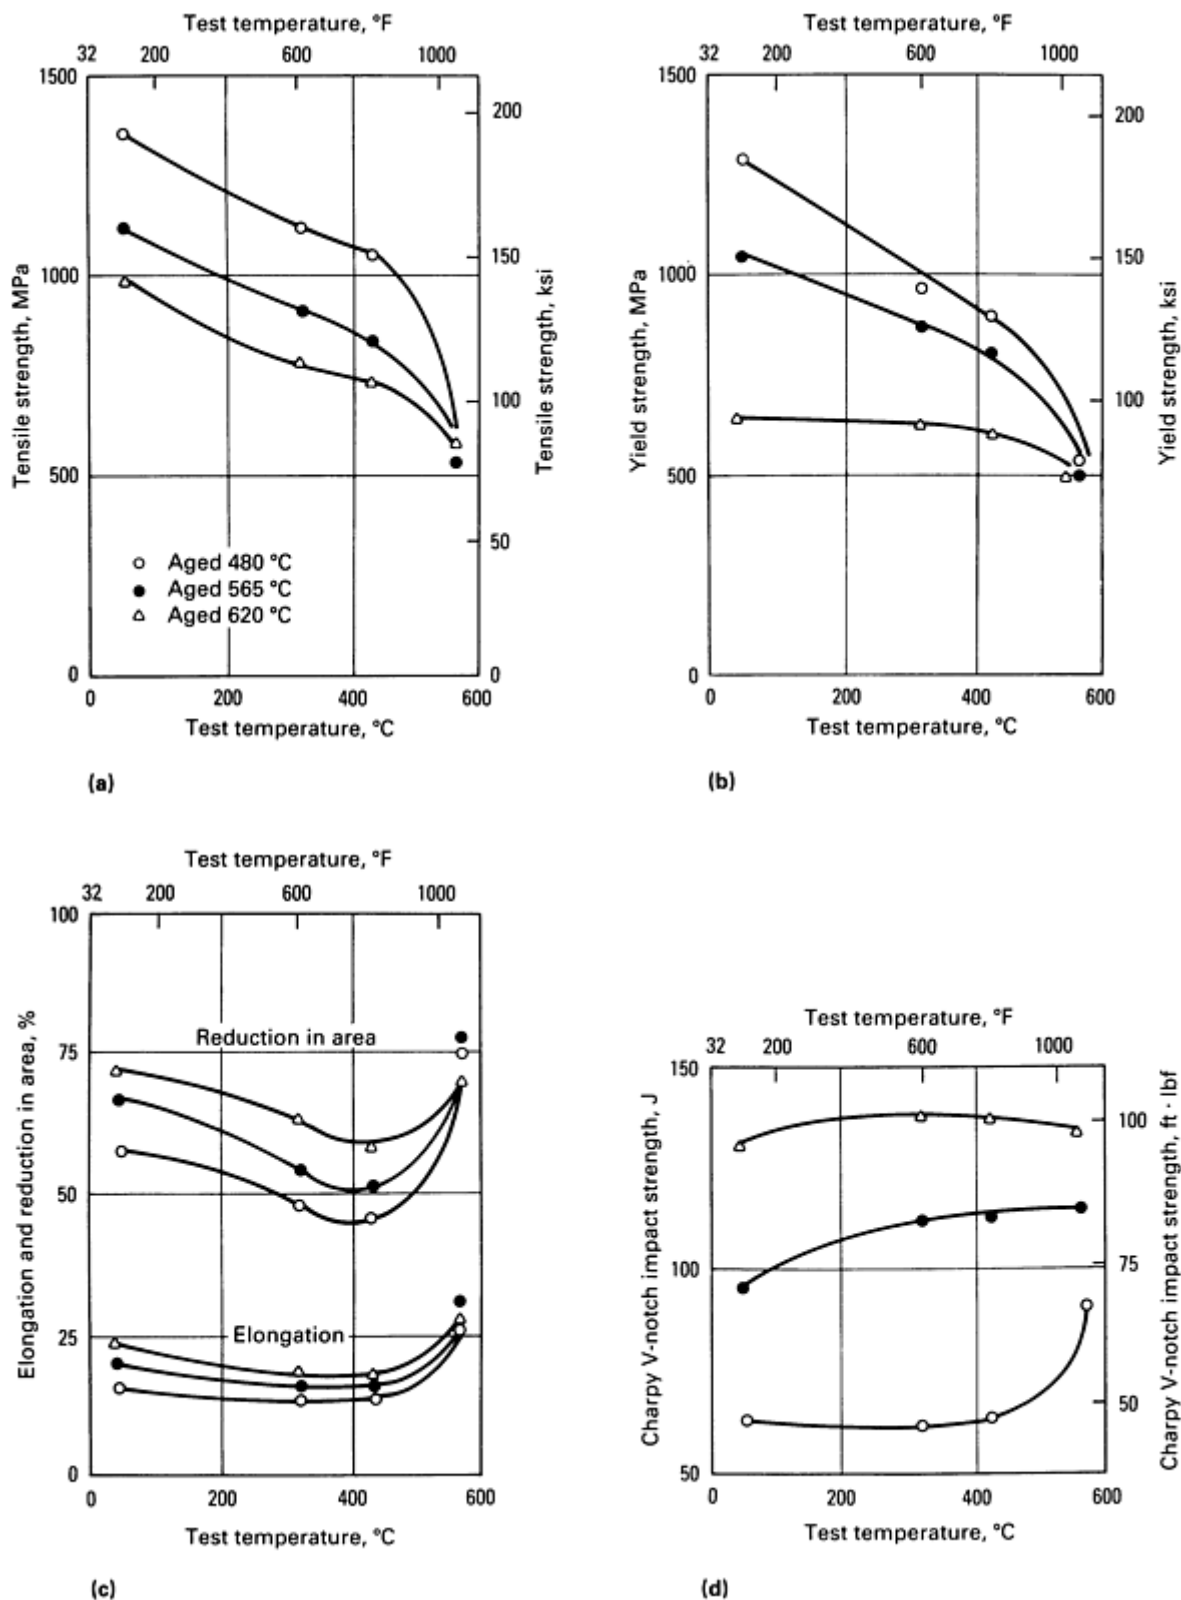

Fig. 24 Effect of temperature on (a) tensile strength, (b) yield strength, (c) elongation, and (d) impact toughness of Custom 450. Material used for testing was round bar stock 25 mm (1 in.) in diameter that had been solution treated by heating 1 h at 1040 °C (1900 °F) and water quenching.

Precipitation-hardening martensitic stainless steels are used for short-time elevated-temperature exposures in industrial and military applications for which resistance to corrosion and high mechanical properties at temperatures up to 425 °C (800 °F) are necessary. Typical uses include valve parts, ball bearings, forgings, turbine blades, mandrels, conveyor chain, miscellaneous hardware, and mechanical and structural components for aircraft.

Welding. All of these alloys are martensitic in the annealed condition and, because of their low carbon levels, are readily weldable with minimal danger of cracking. Any of the standard welding procedures, such as gas tungsten arc, gas metal arc, covered electrode, and resistance welding, may be used. No preheating is required because the very low carbon content of these alloys restricts the hardness of rapidly metal and reduces the possibility of crack formation in weld metal and in the heat-affected zone.

Elevated-Temperature Properties of Stainless Steels

Precipitation-Hardening Semiaustenitic Stainless Steels

The precipitation-hardening semiaustenitic heat-resistant stainless steels are modifications of standard 18-8 austenitic stainless steels. Nickel contents are lower, and such elements as aluminum, copper, molybdenum, and niobium are added. These steels are used at temperatures up to 480 °C (900 °F).

Heat Treatment. Typical schedules for heat treating precipitation-hardening alloys are given in Table 6. These alloys are solution annealed above 1040 °C (1900 °F) and in this condition can be formed, stamped, stretched, and otherwise cold worked to about the same extent as can 18-8 alloys, although they are less ductile and may require intermediate annealing.

Table 6 Heat-treating schedules for precipitation-hardening semiaustenitic stainless steels

Alloy	Mill heat treatment (solution anneal)	Fabrication	Conditioning and hardening treatments	Aging or tempering treatment
17-7 PH	1065 °C (1950 °F), air cool	Forming, welding	10 min at 955 °C (1750 °F), air cool, 8 h at -75 °C (-100 °F)	1 h at 510, 565, or 620 °C (950, 1050, or 1150 °F)
			1 $\frac{1}{2}$ h at 760 °C (1400 °F), air cool to 15 °C (60 °F), hold $\frac{1}{2}$ h	1 h at 510, 565, or 620 °C (950, 1050, or 1150 °F)
15-7 Mo	1065 °C (1950 °F), air cool	Forming, welding	10 min at 955 °C (1750 °F), air cool, 8 h at -75 °C (-100 °F)	1 h at 510, 565 or 620 °C (950, 1050, or 1150 °F)
			1 $\frac{1}{2}$ h at 790 °C (1450 °F), air cool to 15 °C (60 °F), hold $\frac{1}{2}$ h	1 h at 510, 565, or 620 °C (950, 1050, or 1150 °F)
AM-350	1040-1080 °C (1900-1975 °F), air cool	Forming, welding	930 °C (1710 °F), air cool, 3 h at -75 °C (-100 °F)	3 h at 455 or 540 °C (850 or 1000 °F)
			3 h at 745 °C (1375 °F), air cool to 27 °C (80 °F) max	3 h at 455 °C (850 °F)

AM-355	3 h at 775 °C (1425 °F), oil or water quench to 27 °C (80 °F) max, 3 h at 580 °C (1075 °F), air cool	Machining and other	1040 °C (1900 °F), water quench, 3 h at -75 °C (-100 °F), reheat to 955 °C (1750 °F), air cool, 3 h at -75 °C (-100 °F)	3 h at 455 or 540 °C (850 or 1000 °F)
--------	--	---------------------	---	---------------------------------------

All the semiaustenitic stainless steels can also be used in the cold-worked condition, in either sheet or wire form. Cold working causes partial transformation of the rather unstable austenite to martensite because of plastic deformation. Aging or tempering is performed after cold working.

Mechanical Properties. Typical short-time tensile, rupture, and creep properties of several precipitation-hardening semiaustenitic alloys are compared in Fig. 25. Different hardening heat treatments may produce a wide variety of useful properties for the same alloy. For example, the PH 15-7 Mo alloy treated to condition RH950 has a higher rupture strength than the same alloy treated to TH1050 (Fig. 26). Strengths also degrade after long-term exposure at elevated temperature because of overaging (coarsening) of precipitates.

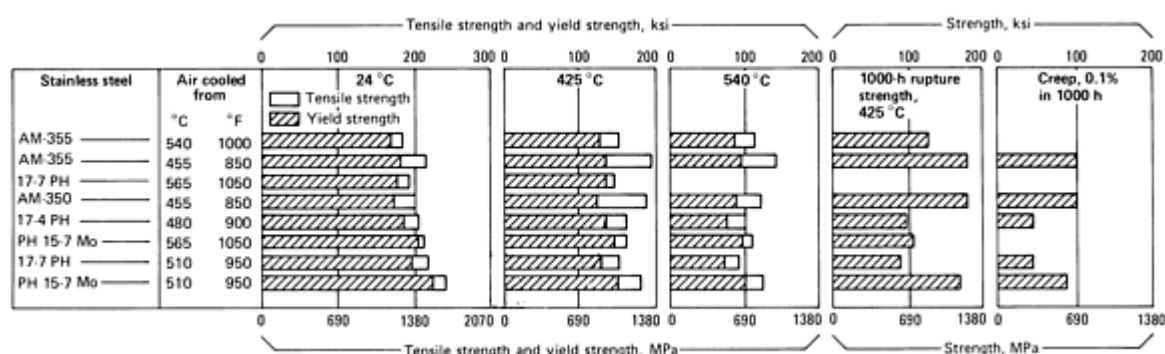

Fig. 25 Short-time tensile, rupture, and creep properties of precipitation-hardening stainless steels. AM-355 was finish hot worked from a maximum temperature of 980 °C (1800 °F), reheated to 930 to 955 °C (1710 to 1750 °F), water quenched, treated at -75 °C (-100 °F), and aged at 540 and 455 °C (1000 and 850 °F). 17-7 PH and PH 15-7 Mo were solution treated at 1040 to 1065 °C (1900 to 1950 °F). 17-7 PH (TH1050) and PH 15-7 Mo (TH1050) were reheated to 760 °C (1400 °F), air cooled to 15 °C (60 °F) within 1 h, and aged 90 min at 565 °C (1050 °F). 17-7 PH (RH950) and PH 15-7 Mo (RH950) were reheated to 955 °C (1750 °F) after solution annealing, cold treated at -75 °C (-100 °F), and aged at 510 °C (950 °F). 17-4 PH was aged at 480 °C (900 °F) after solution annealing. AM-350 was solution annealed at 1040 to 1065 °C (1900 to 1950 °F), reheated to 930 °C (1710 °F), air cooled, treated at -75 °C (-100 °F), and then aged at 455 °C (850 °F).

Fig. 26 Stress-rupture curves of PH 15-7 Mo stainless steel in the TH1050 and RH950 condition

Compressive and tensile yield strengths are approximately equal for all precipitation-hardened steels. For sheet, yield strengths of specimens taken transverse and parallel to the direction of rolling may vary appreciably. The magnitude of this effect varies from grade to grade and with the heat treatment for a given grade.

Welding. The precipitation-hardening stainless steels in either the annealed or the hardened condition can be welded by any of the processes used for welding 18-8 (300-series) stainless steel. These steels are less ductile and more notch sensitive than ventional 18-8 grades and require more care to prevent stress concentrations at corners and notches.

The gas-shielded tungsten arc process has been satisfactory for welding large assemblies of sheet and forgings that are subsequently aged. Postweld annealing is desirable.

A complete cycle of heat treatment, including high-temperature solution annealing, is desirable after welding. Strength and ductility in fully heat-treated fusion welds are superior to these properties in material hardened before welding and not heat treated after welding. Joint efficiencies near 90% have been reported for welded joints fully heat treated after welding.

The precipitation-hardening steels can be spot welded by the same technique used for 18-8 steels. This may be done before or after precipitation hardening. The minimum shear requirements for stainless steel at 1035 MPa (150 ksi) can be obtained.

Applications. Precipitation-hardening steels are used for industrial and military applications that require resistance to corrosion as well as high mechanical properties at temperatures up to 425 °C (800 °F). Typical uses of these steels include landing-gear hooks, poppet valves, fuel tanks, hydraulic lines, hydraulic fittings, compressor casings, miscellaneous hardware, and structural components for aircraft. The higher-carbon grade (0.13%) is used for compressor blades, spacers, frames and casings for gas turbines, oil well drill rods, and rocket casings.

Precipitation-hardening steels can be cold rolled and tempered. Work-hardening rates are higher than for type 301 stainless steel and can be varied by regulating the annealing temperature. Compared with cold-rolled 301, cold-rolled precipitation-hardened steels have higher ductility at a given strength level, higher modulus of elasticity in compression in the rolling direction, and less reduction in strength with increasing temperature.

Elevated-Temperature Properties of Stainless Steels

Austenitic Stainless Steels

Austenitic stainless steels comprise a group of iron-base alloys that contain 16 to 25% Cr and residual to 20% Ni. Some alloys may contain as much as 18% Mn. These stainless steels are not hardenable by heat treatment but can be hardened by cold work. However, the effect of cold work on strength is lost after elevated-temperature exposure (Fig. 2) because of recrystallization.

The austenitic stainless steels listed in Table 1 can be grouped into three categories, based primarily on composition:

- *300-series alloys*, which are essentially chromium-nickel and chromium-nickel-molybdenum austenitic stainless steels to which small amounts of other elements have been added
- *19-9 DL, 19-9 DX, and 17-14-CuMo*, all of which contain 1.25 to 2.5% Mo and 0.3 to 0.55% Ti. Other elements used include 1.25% W and 3% Cu in 17-14-CuMo
- *Chromium-nickel-molybdenum alloys*, which include types 201 and 202; 21-6-9; Nitronics 32, 33, 50, and 60; and Carpenter 18-18 Plus. These alloys contain 5 to 18% Mn and 0.10 to 0.50% N

Austenitic stainless steels are noted for high strength and for exceptional toughness, ductility, and formability. As a class, they exhibit considerably better corrosion resistance than martensitic or ferritic steels and also have excellent strength and oxidation resistance at elevated temperatures.

Solution heat treatment of these alloys is done by heating to about 1095 °C (2000 °F), followed by rapid cooling. Carbides that are dissolved at these temperatures may precipitate at grain boundaries upon exposure to temperatures from 425 to 870 °C (800 to 1600 °F), causing chromium depletion in grain-boundary regions. In this condition, the metal is sensitive to intergranular corrosion in oxidizing acids. The precipitation of chromium carbides can be controlled by reducing carbon content, as in types 304L and 316L, or by adding the stronger carbide formers titanium and niobium, as in types 321 and 347. These alloys are normally purchased and used in the annealed condition. The reduced carbon in solution in the low-carbon (304L, 316L) and stabilized grades (321, 347) results in reduced creep strength and creep-rupture strength.

H grades. For the best creep strength and creep-rupture strength, the H grades of austenitic stainless steels are specified. These steels have carbon contents of 0.04 to 0.10% (Table 1) and are solution annealed at temperatures high enough to produce improved creep properties. The minimum annealing temperatures specified in ASTM A 312 and A 240 for H grades in general corrosion service are:

- 1040 °C (1900 °F) for hot-finished or cold-worked 304H and 316H steels
- 1095 °C (2000 °F) for cold-worked 321H, 347H, and 348H steels
- 1050 °C (1905 °F) for hot-finished 321H, 347H, and 348H steels

The stabilized grades (such as 321H, 347H, and 348H) have additions of strong carbide-forming elements, which lower the amount of dissolved carbon at a given annealing temperature (Fig. 27). The carbide formers in the stabilized grades,

such as niobium in 347H, increase the resistance to intergranular corrosion by making less dissolved carbon available for chromium carbide formation, thereby preventing the depletion of chromium in grain-boundary regions.

Fig. 27 Dissolved carbon under equilibrium conditions calculated from the solubility products for a type 347 (0.054% C, 0.76% Nb), a type 321 (0.054% C, 0.42% Ti), and unstabilized 18Cr-8Ni stainless steel

When intergranular corrosion is of concern, annealing temperatures must be low enough to keep dissolved carbon at low levels. Type 347H tube, for example, at the minimum annealing temperature of 1095 °C (2000 °F) (specified in ASME SA213) would have only about 0.01% soluble carbon. (Fig. 27), and the alloy should be stabilized against chromium depletion in the grain boundaries. However, annealing temperatures above 1065 °C (1950 °F) may still impair the intergranular corrosion resistance of stabilized grades such as 321, 321H, 347, 347H 348, and 348H. When type 321H and 347H are used in applications where intergranular corrosion may be a problem, it is possible to apply an additional stabilizing treatment at a temperature near 900 °C (1650 °F) to reduce free carbon content by carbide precipitation.

Lower annealing temperatures improve resistance to intergranular corrosion but also reduce creep strength and creep-rupture strength. Figure 28 shows the creep-rupture strength of 347H tube treated at different annealing temperatures. In

applications where intergranular corrosion is not a concern, better creep properties can be obtained with higher annealing temperatures. Types 321H and 347H, for example, are solution annealed at temperatures above 1120 °C (2050 °F) and 1150 °C (2100 °F), respectively, in order to put carbides in solution and to coarsen the grain structure, thereby ensuring the best creep strength and creep-rupture strength.

Fig. 28 Stress-rupture strength of type 347H stainless steel treated at different solution-annealing temperatures

Tensile Properties. Typical mechanical property data for austenitic stainless steels are given in Fig. 29. Room-temperature tensile properties of annealed 300-series alloys are similar. At higher testing temperatures (425 and 650 °C, or 800 and 1200 °F), types 321, 347, and 309 appear to have yield strengths somewhat higher than those of types 304, 310, and 316. Types 309, 310, and 316 have the highest tensile strengths at 650 °C (1200 °F).

Fig. 29 Effect of testing temperature on tensile properties of austenitic stainless steels. Heat treating schedules were as follows. Type 304: 1065 °C (1950 °F), water quench. Type 309: 1090 °C (2000 °F), water quench. Type 310: 1120 °C (2050 °F), water quench. Type 316: 1090 °C (2000 °F), water quench. Type 321: 1010 °C (1850 °F), water quench. Type 347: 1065 °C (1950 °F), water quench. 19-9 DX and 19-9 DL: 705 °C (1300 °F), water quench.

°F), air cool. Type 216: 1065 °C (1950 °F), water quench. 21-6-9: 1065 °C (1950 °F), water quench. Nitronic 33: 1065 °C (1950 °F), water quench. Nitronic 50: 1090 °C (2000 °F), water quench. Nitronic 60: 1065 °C (1950 °F), water quench. Carpenter 18-18 Plus: 1065 °C (1950 °F), water quench

Tensile and yield strengths of 19-9 DL and 19-9 DX are higher than those of any 300-series alloy. However, 19-9 DL and 19-9 DX are heat treated at 705 °C (1300 °F), compared with an average of 1065 °C (1950 °F) for 300-series alloys. Also, 19-9 DL and 19-9 DX are normally strengthened by controlled amounts of hot and cold work.

Tensile and yield strengths of chromium-nickel-molybdenum alloys are higher than those of 300-series alloys at both room and elevated temperatures. Carpenter 18-18 Plus exhibits the highest room-temperature tensile strength, whereas Nitronic 50 has the highest tensile strength at 650 °C (1200 °F).

Stress-rupture properties of various stainless steels in the 300 series are shown in Fig. 5. The H grades of type 347 and 316 appear to be the two strongest alloys over a range of temperatures. Stress-rupture times and creep rates of these two austenitic stainless steels are shown in Fig. 30.

Fig. 30 Stress-rupture times and creep rates for annealed (a) type 347 stainless steel and (b) type 316 stainless steel. Source: Ref 22

The 19-9 DL and 19-9 DX alloys have rupture strengths superior to those of all 300-series alloys over the limited temperature and time range for which rupture data are available (1000-h rupture strength at 540 to 815 °C, or 1000 to 1500 °F) (Fig. 31). At longer times or higher temperatures, the 300 series may be superior. For the time-temperature range in Fig. 31, the chromium-nickel-molybdenum alloys have higher stress-rupture capabilities than do 300-series alloys, with the following exceptions: type 316 is superior to 21-6-9, and both 316 and 347 are stronger than Nitronic 60. The spread in rupture strength capability among these alloys is greater at the lower testing temperatures (540 to 700 °C, or 1000 to 1300 °F) and becomes progressively smaller as temperature is increased to approximately 980 °C (1800 °F), where all the alloys exhibit 1000-h rupture stresses of about 7 to 10 MPa (1 to 1.5 ksi). Types 304 and 310 have the lowest stress-rupture strengths.

Fig. 31 Stress-rupture plots for various austenitic stainless steels. Heat treating schedules were as follows. Type 304: 1065 °C (1950 °F), water quench. Type 309: 1090 °C (2000 °F), water quench. Type 310: 1120 °C (2050 °F), water quench. Type 316: 1090 °C (2000 °F), water quench. Type 347: 1065 °C (1950 °F), water quench. 21-6-9: 1065 °C (1950 °F), water quench. 19-9 DX and 19-9 DL: for tests above 705 °C (1300 °F), 1065 °C (1950 °F) and water quench, then 705 °C (1300 °F) and air cool; for tests below 705 °C (1300 °F), 705 °C (1300 °F) and air cool. Nitronic 50: 1090 °C (2000 °F), water quench. Nitronic 60: 1065 °C (1950 °F), water quench. Larson-Miller parameter = $T/1000 (20 + \log t)$ where T is temperature in °R and t is time in h. All data taken from 1000-h tests

Aging and the degradation of mechanical properties occur in austenitic steel because of two principal factors:

- Precipitation reactions that occur during prolonged exposure at elevated temperatures
- Environmental effects, such as corrosion or nuclear irradiation

The precipitation reactions in austenitic stainless steels that occur during prolonged exposure at elevated temperatures are complex, but some general guidance to the precipitates formed can be gained by reference to constitutive diagrams in Ref 23. The precipitates formed at temperatures in the range of about 500 to 600 °C (930 to 1110 °F) are predominantly carbides, while at higher temperatures they are in the form of intermetallic phases. Although about 30 phases have been identified in stainless steels, the predominant precipitates found in plant-serviced alloys and weld metals exposed to temperatures of about 550 °C (1020 °F) are $M_{23}C_6$ and MC carbides in unstabilized and stabilized steels, respectively. At temperatures above 600 °C (1110 °F), σ phase and Fe_2Mo are also formed. The aging process also tends to occur more rapidly in weld metals that contain δ -ferrite (Ref 23).

Environmental effects on aging can be classified as either surface effects or bulk effects. Surface effects include oxidation and carburization, while bulk effects include changes in properties from nuclear irradiation (see the article "Effect of Neutron Irradiation on Properties of Steels" in this Volume).

Impact Toughness. Solution-annealed austenitic stainless steels are very tough, and their impact energies are very high. However, following elevated-temperature thermal aging, the impact energy decreases with increasing time at temperature. The impact energy of AISI type 316 stainless steel (Fig. 32) shows a continuous fall with increasing exposure time and temperature in the range of 650 to 850 °C (1200 to 1560 °F). Service-exposed type 316 stainless steel exhibited impact energies of 80 and 300 J (60 and 220 ft · lbf) in the serviced and resolution heat-treated conditions, respectively, when tested at room temperature (Ref 23).

Fig. 32 Room-temperature impact toughness of 316 stainless steel after aging at indicated temperatures. Source: Ref 23

Duplex stainless steels, with δ -ferrite in an austenite matrix, have improved resistance to stress-corrosion cracking and increased yield and tensile strengths. A further advantage of the presence of σ -ferrite is that it causes grain refinement, which produces additional strengthening. Further refining of the grain size can be achieved by a controlled-rolling treatment, using hot working in the range of 900 to 950 °C (1650 to 1740 °F) or even lower temperatures. This causes a very fine dispersion of ferrite and austenite, in approximately equal proportions, which can give yield strengths in excess of 450 MPa (65 ksi). Duplex steels, however, require a careful balance of the ferrite- and austenite-forming elements (see the article "Cast Stainless Steels" in this Volume). The duplex steels are susceptible to 885 °F embrittlement at 370 to 480 °C (700 to 900 °F) and to σ formation at 650 to 815 °C (1200 to 1500 °F). For this reason, they are not very suitable for high-temperature applications.

Fatigue properties at elevated temperatures are dependent on several variables including strain range, temperature, cyclic frequency, hold times, and the environment. The fatigue design curves in Fig. 33(a) show the simple case of pure fatigue (that is continuous cycles without hold times) for 304 and 316 stainless steel. These design curves (from Code Case N-47 in the ASME Boiler Code) have a built-in-factor of safety and are established by applying a safety factor of 2 with respect to strain range or a factor of 20 with respect to the number of cycles, whichever gives the lower value. The creep-life-fraction is determined by the time-life fraction per cycle using assumed stresses 1.1 times the applied stress and the minimum stress-rupture curves incorporated in the code. The total damage must not exceed the envelope defined by the bilinear damage curve shown in Fig. 34.

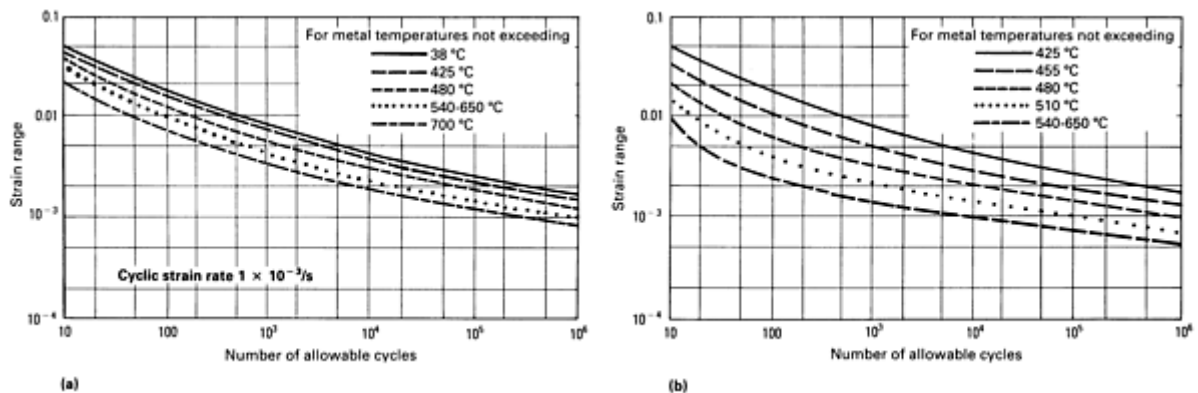

Fig. 33 Design fatigue-strain range curves for 304 and 316 stainless steel. (a) Design curves with continuous cycling (pure fatigue). (b) Design curves with hold times (creep-fatigue interaction)

Fig. 34 Comparison of linear damage rule of creep-fatigue interaction with design envelopes in ASME Code Case N-47 for 304 and 316 stainless steel. Creep-damage fraction = time/time-to-rupture (multiplied by a safety factor). Fatigue-damage fraction = number of cycles/cycles to failures (multiplied by a safety factor).

The design curves in Fig. 33(a) are based on a strain rate of $1 \times 10^{-3}/s$. If the strain rate decreases, fatigue life also decreases. In Fig. 35, for example, the fatigue lives of several stainless steels are shown for continuous cycling at two different strain rates. Fatigue life is reduced with a lower strain rate, while grain size has little effect on fatigue life when life is determined from pure fatigue (or continuous cycling).

Fig. 35 Effect of strain rate and grain size on the fatigue life of various stainless steels at elevated temperatures. Grain size has the greatest influence on fatigue life when hold times are increased. Test conditions: total strain range = 1.0%; test temperature, 593 to 600 °C (1100 to 1110 °F). Source: Ref 24

When hold times are introduced, a different set of design curves is used (Fig. 33b) to determine the allowable fatigue-life fraction (creep-life fraction is determined the same way as for continuous cycling). These allowable fatigue-life curves are a more conservative set of curves than those of Fig. 33(a). They incorporated the effect of creep damage by applying a fatigue life reduction factor, which includes hold time effects in addition to the factor of safety (2 in strength and 20 in cycles, whichever gives the lower value). Figure 36 compares the 540 to 650 °C (1000 to 1200 °F) design curve in Fig. 33(b) with actual fatigue life results from testing 316 stainless at 593 °C (1100 °F) and various hold times. When hold times are introduced, the influence of grain size may also be more pronounced (Fig. 35).

Fig. 36 Influence of tensile hold times at peak strain on failure life of a single heat of type 316 stainless steel tested at 593 °C (1100 °F). Source: Ref 24

Fatigue Crack Growth. Although *S-N* curves have been used in the past as the basic design tool against fatigue, their limitations have become increasingly obvious. One of the more serious limitations is that they do not distinguish between crack initiation and crack propagation. Particularly in the low-stress regions, a large fraction of the life of a component may be spent in crack propagation, allowing crack tolerance over a large portion of the life. Engineering structures often contain flaws or cracklike imperfections that may altogether eliminate the crack initiation step. A methodology that quantitatively describes crack growth as a function of the loading variables is, therefore, of great value in design and in assessing the remaining lives of components.

Because fatigue crack growth rates are obtained at various ΔK and temperature ranges, it is difficult to compare the various types of materials directly. At a constant ΔK (arbitrarily chosen as $30 \text{ MPa}\sqrt{m}$, or $27 \text{ ksi}\sqrt{in}$), a clear trend of crack growth rate increase with increasing temperature can be seen (Fig. 37). In this figure it can be seen that at temperatures up to about 50% of the melting point (550 to 600 °C, or 1020 to 1110 °F), the growth rates are relatively insensitive to temperature, but sensitivity increases rapidly at higher temperatures. The crack growth rates for all the materials at temperatures up to 600 °C (1110 °F) relative to the room-temperature rates can be estimated by a maximum correlation factor of 5 (2 for ferritic steels).

Fig. 37 Variation of fatigue crack growth rates as a function of temperature at $\Delta K = 30 \text{ MPa } \sqrt{m}$ ($27 \text{ ksi } \sqrt{in}$). Source: Ref 2

Applications that use the heat-resisting capabilities of austenitic stainless steels to advantage include furnace parts, heat exchanger tubing, steam lines, exhaust systems in reciprocating engines and gas turbines, afterburner parts, and similar parts that require strength and oxidation resistance.

Type 304 has good resistance to atmospheric corrosion and oxidation. Types 309 and 310 rank higher in these properties because of their higher nickel and chromium contents. Type 310 is useful where intermittent heating and cooling are encountered, because it forms a more adherent scale than does type 309. Types 309 and 310 are used for parts such as firebox sheets, furnace linings, boiler baffles, thermocouple wells, aircraft cabin heaters, and jet engine burner liners.

The austenitic stainless steels may become susceptible to intergranular corrosion in some environments. This occurs when these steels are exposed to temperatures between 500 and 900 °C (950 and 1650 °F) and carbon diffuses to the grain boundaries to form chromium carbides. The formation of these carbides can significantly reduce the amount of free chromium in the alloy, thus impairing the corrosion resistance of the grain boundaries. The intergranular corrosion that occurs in the heat-affected zones of welds is often called weld knife edge attack. Types 321 and 347 (when correctly heat treated to form titanium and niobium carbides, respectively) and the naturally low-carbon grades 304L and 316L are resistant to intergranular corrosion. Intergranular attack is usually limited to aqueous environments and is covered in more detail in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. When types 321H and 347H are used in applications where intergranular corrosion may be a problem, it is possible to apply an additional stabilizing heat treatment at a temperature near 900 °C (1650 °F) to produce stable titanium and niobium carbides and thus reduce the free carbon content.

Types 321 and 347 can be used where solution treatment after welding is not feasible, such as in steam lines and superheater tubes and exhaust systems in reciprocating engines and gas turbines that operate at temperatures from 425 to 870 °C (800 to 1600 °F). The low-carbon types 304L and 316L are used for similar applications but are more susceptible to intergranular attack during long exposure to high temperature.

Type 316 has better mechanical properties than 304 or 321 and is more resistant to corrosion in some media, such as fatty acids at elevated temperature and mild sulfuric acid solutions. The tensile and yield strengths of 304, 304L, 316, and 316L

can be increased by alloying these grades with nitrogen. These modifications are designated as 304N (UNS S30451), 304LN (UNS S30454), 316N (UNS S31651), and 316LN (UNS S31653).

Introduction

SUPERALLOYS are heat-resisting alloys based on nickel, nickel-iron, or cobalt that exhibit a combination of mechanical strength and resistance to surface degradation. Superalloys are primarily used in gas turbines, coal conversion plants, and chemical process industries, and for other specialized applications requiring heat and/or corrosion resistance. The modern high-performance aircraft (jet) engine could not operate without the major advances made in superalloy development over the past 50 years. A noteworthy feature of nickel-base alloys is their use in load-bearing applications at temperatures in excess of 80% of their incipient melting temperatures, a fraction that is higher than for any other class of engineering alloys.

This article focuses on the properties of conventional wrought superalloys based on nickel, iron, and cobalt, as well as on the properties of alloys produced from powder. The powder metallurgy (P/M) category includes alloys that were originally developed as casting alloys; new alloy compositions developed specifically to benefit from powder processing; and oxide dispersion strengthened (ODS) alloys (particularly those produced by mechanical alloying). The ODS alloys based on nickel and iron have been commercialized, whereas those based on cobalt have not. Other types of superalloys are described in the articles "Polycrystalline Cast Superalloys" and "Directionally Solidified and Single-Crystal Superalloys" in this Volume.

Applications of superalloys are categorized below; the bulk of tonnage is used in gas turbines:

- *Aircraft gas turbines*: disks, combustion chambers, bolts, casings, shafts, exhaust systems, cases, blades, vanes, burner cans, afterburners, thrust reversers
- *Steam turbine power plants*: bolts, blades, stack gas reheaters
- *Reciprocating engines*: turbochargers, exhaust valves, hot plugs, valve seat inserts
- *Metal processing*: hot-work tools and dies, casting dies
- *Medical applications*: dentistry uses, prosthetic devices
- *Space vehicles*: aerodynamically heated skins, rocket engine parts
- *Heat-treating equipment*: trays, fixtures, conveyor belts, baskets, fans, furnace mufflers
- *Nuclear power systems*: control rod drive mechanisms, valve stems, springs, ducting
- *Chemical and petrochemical industries*: bolts, fans, valves, reaction vessels, piping, pumps
- *Pollution control equipment*: scrubbers
- *Metals processing mills*: ovens, afterburners, exhaust fans
- *Coal gasification and liquefaction systems*: heat exchangers, reheaters, piping

Many technical considerations, such as formability, strength, creep resistance, fatigue strength, and surface stability, must be evaluated when selecting superalloy for any of the applications identified above. Unfortunately, those compositional and microstructural variables that benefit one property may result in undesirable performance in another area. For example, fine grain size is desirable for low-temperature tensile strength, fatigue crack initiation resistance, and high-temperature formability, but creep resistance is usually adversely affected. Similarly, high chromium contents in nickel alloys improve the resistance to oxidation and hot corrosion, but result in lower tensile and creep strengths and promote the formation of σ phase. Further, the more temperature resistant the alloy, the more likely it is to be segregation prone and, perhaps, brittle, and thus formable only by casting to shape or by using powder processing. For these and other compelling reasons, the interplay between composition, microstructure, consolidation method, mechanical properties, and surface stability is emphasized in this article.

Wrought and P/M Superalloys

N. S. Stoloff, Rensselaer Polytechnic Institute

Wrought Nickel Alloys

Nickel alloys in commercial service and under development range from single-phase alloys to precipitation-hardened superalloys and oxide dispersion strengthened alloys and composites, the latter of which is described in the section "P/M Alloys" in this article. Nickel-base superalloys are the most complex, the most widely used for the hottest parts, and, to many metallurgists, the most interesting of all superalloys. They currently constitute over 50% of the weight of advanced aircraft engines. Their use in cast form extends to the highest homologous temperature of any common alloy system (see the article "Polycrystalline Cast Superalloys" in this Volume).

The principal characteristics of nickel as an alloy base are the high phase stability of the face-centered cubic (fcc) nickel matrix and the capability to be strengthened by a variety of direct and indirect means. Further, the surface stability of nickel is readily improved by alloying with chromium and/or aluminum. In order to adequately describe mechanical behavior, however, it is first necessary to consider the composition and microstructure of the various classes of nickel alloys.

Chemical Composition

The compositions of many representative nickel-base wrought alloys are listed in Table 1. They can be categorized as nickel-iron-base alloys, in which nickel is the major solute element, or nickel-base, in which at least 50% Ni is present. The nickel-iron alloys are discussed in detail in a later section. The nickel-base superalloys discussed below are considered to be complex because they incorporate as many as a dozen elements. In addition, deleterious elements such as silicon, phosphorus, sulfur, oxygen, and nitrogen must be controlled through appropriate melting practices. Other trace elements, such as selenium, bismuth, and lead, must be held to very small (ppm) levels in critical parts.

(a) Ref 2 (1984 data). Bal, balance,

Many wrought nickel-base superalloys contain 10 to 20% Cr, up to about 8% Al and Ti combined, 5 to 15% Co, and small amounts of boron, zirconium, magnesium, and carbon. Other common additions are molybdenum, niobium, and tungsten, all of which play dual roles as strengthening solutes and carbide formers. Chromium and aluminum are also necessary to improve surface stability through the formation of Cr_2O_3 and Al_2O_3 , respectively. The functions of the various elements in nickel alloys are summarized in Table 2, where in addition, they are compared to iron- and cobalt-base alloys. Other alloys that have been developed primarily for low-temperature service, often in corrosive environments (refer to the Hastelloy series and Inconel 600 shown in Table 1), are likely to contain chromium, molybdenum, iron, or tungsten in solution, with little or no second phase present.

Table 2 Role of elements in superalloys

Effect	Iron base	Cobalt base	Nickel base
Solid-solution strengtheners	Cr, Mo	Nb, Cr, Mo, Ni, W, Ta	Co, Cr, Fe, Mo, W, Ta
Fcc matrix stabilizers	C, W, Ni	Ni	...
Carbide form			
MC Type	Ti	Ti, Ta, Nb	W, Ta, Ti, Mo, Nb

M ₂₃ C ₆ type	Cr	Cr	Cr, Mo, W
M ₆ C type	Mo	Mo, W	Mo, W
Carbonitrides			
M(CN) type	C, N	C, N	C, N
Forms γ' Ni ₃ (Al, Ti)	Al, Ni, Ti	...	Al, Ti
Retards formation of hexagonal η (Ni ₃ Ti)	Al, Zr
Raises solvus temperature of γ'	Co
Hardening precipitates and/or intermetallics	Al, Ti, Nb	Al, Mo, Ti ^(a) W, Ta	Al, Ti, Nb
Forms γ'' (Ni ₃ Nb)	Nb
Oxidation resistance	Cr	Al, Cr	Al, Cr
Improves hot corrosion resistance	La, Y	La, Y, Th	La, Th
Sulfidation resistance	Cr	Cr	Cr
Increases rupture ductility	B	B, Zr	B^(b), Zr
Causes grain-boundary segregation	B, C, Zr

Facilitates working	...	Ni ₃ Ti	...
---------------------	-----	--------------------	-----

Source: Ref 3

(a) Hardening by precipitation of Ni₃Ti also occurs if sufficient Ni is present.

(b) If present in large amounts, borides are formed.

Microstructure

The major phases that may be present in nickel-base alloys are:

- *Gamma matrix*, γ , in which the continuous matrix is an fcc nickel-base nonmagnetic phase that usually contains a high percentage of solid-solution elements such as cobalt, iron, chromium, molybdenum, and tungsten. All nickel-base alloys contain this phase as the matrix
- *Gamma prime*, γ' , in which aluminum and titanium are added in amounts required to precipitate fcc γ' (Ni₃Al,Ti), which precipitates coherently with the austenitic gamma matrix. Other elements, notably niobium, tantalum, and chromium, also enter γ' . This phase is required for high-temperature strength and creep resistance.
- *Gamma double prime*, γ'' , in which nickel and niobium combine in the presence of iron to form body-centered tetragonal (bct) Ni₃Nb, which is coherent with the gamma matrix, while including large mismatch strains of the order of 2.9%. This phase provides very high strength at low to intermediate temperatures, but is unstable at temperatures above about 650 °C (1200 °F). This precipitate is found in nickel-iron alloys.
- *Grain boundary γ'* , a film of γ' along the grain boundaries in the stronger alloys, produced by heat treatments and service exposure. This film is believed to improve rupture properties
- *Carbides*, in which carbon that is added in amounts of about 0.02 to 0.2 wt% combines with reactive elements, such as titanium, tantalum, hafnium, and niobium, to form metal carbides (MC). During heat treatment and service, these MC carbides tend to decompose and generate other carbides, such as M₂₃C₆ and/or M₆C, which tend to form at grain boundaries. Carbides in nominally solid-solution alloys may form after extended service exposures
- *Borides*, a relatively low density of boride particles formed when boron segregates to grain boundaries
- *Topologically close-packed (TCP)-type phases*, which are platelike or needle-like phases such as σ , μ , and Laves that may form for some compositions and under certain conditions. These cause lowered rupture strength and ductility. The likelihood of their presence increases as the solute segregation of the ingot increases

In solid-solution alloys such as Inconel 600 and Hastelloy C (Table 1), only the gamma matrix is present. In nickel-base superalloys, however, the above phases, except γ'' , are generally present. Solution treatments are designed to dissolve most precipitated phases (see Table 3). On the other hand, several nickel-iron superalloys, such as Inconel 706 and Inconel 718, contain γ'' Ni₃Nb as the principal precipitate, as well as γ' . Further, oxide dispersion strengthened alloys contain a few volume percent of a dispersed phase such as Y₂O₃ in a γ - γ' matrix, while composites (mechanically incorporated) contain tungsten or tungsten alloy fibers.

Table 3 Solution treatments for selected wrought nickel-base superalloys

As used in blades or in creep-limiting applications

Alloy	Solution temperature ^(a)	Time, h
-------	-------------------------------------	---------

	°C	°F	
Inconel X750	1150	2100	4
Nimonic 90	1080	1975	8
Nimonic 105	1125-1150	2060-2100	4
Udimet 500	1175	2150	2
Udimet 700	1175	2150	4
Waspaloy	1080	1975	4

(a) All materials air cooled after solution treatment

The Gamma Matrix (γ). Pure nickel does not display an unusually high elastic modulus or low diffusivity (two factors that promote creep rupture resistance), but the gamma matrix is readily strengthened for the most severe temperature and time conditions. Some superalloys can be used at $0.85 T_m$ (melting point) and, for times up to 100,000 h, at somewhat lower temperatures. These conditions can be tolerated because of three factors (Ref 4):

- The high tolerance of nickel for solutes without phase instability, because of its nearly filled *d*- shell
- The tendency, with chromium additions, to form Cr_2O_3 having few cation vacancies, thereby restricting the diffusion rate of metallic elements outward and the rate of oxygen, nitrogen, and sulfur inward (Ref 5)
- The additional tendency, at high temperatures, to form Al_2O_3 barriers, which display exceptional resistance to further oxidation

Gamma prime is an intermetallic compound of nominal composition Ni_3Al , which is stable over a relatively narrow range of compositions (Fig. 1). It precipitated as spheroidal particles in early nickel-base alloys, which tended to have a low volume fraction of particles (see Fig. 2a). Later, cuboidal precipitates were noted in alloys with higher aluminum and titanium contents (Fig. 2b). The change in morphology is related to a matrix-precipitate mismatch. It is observed that γ' occurs as spheres for 0 to 0.2% mismatches, becomes cuboidal for mismatches of 0.5 to 1%, and is platelike at mismatches above about 1.25%.

Fig. 1 Nickel-aluminum phase diagram

Fig. 2 Microstructure of (a) fully heat-treated Waspaloy showing MC and $M_{23}C_6$ carbides. 3400 \times . (b) Fully heat-treated Udimet 700 showing cubical γ' . 6800 \times . Source: Ref 6

To understand fully the vital role γ' in the nickel-base superalloys, it is necessary to consider the structure and properties of this phase in some detail. Gamma prime is a superlattice that possesses the Cu_3Au ($L1_2$)-type structure, which exhibits long-range order to its melting point of 1385 °C (2525 °F). It exists over a fairly restricted range of composition, but alloying elements may substitute to a considerable degree for either of its constituents. In particular, most nickel-base alloys are strengthened by a precipitate in which up to 60% of the aluminum can be substituted by titanium and/or niobium. Also, nickel sites in the superlattice may be occupied by iron or cobalt atoms.

Both single crystals and polycrystals of unalloyed γ' exhibit a startling, reversible increase in flow stress between -196 and about 800 °C (-320 and 1470 °F), which is highly dependent on solute content (Ref 7), as shown in Fig. 3. Several other superlattices, such as Ni_3Si , Co_3Ti , Ni_3Ge , and Ni_3Ga , all of $L1_2$ structure, display increasing strength over a temperature range comparable to that of Ni_3Al .

Fig. 3 Flow stress peak in γ' and influence of several solutes. Source: Ref 7

The magnitude and temperature position of the peak in flow stress of γ' may be shifted by alloying elements such as titanium, chromium, and niobium (Fig. 3). There is no simple relation between the magnitude of flow stress increase and the change in the temperature of the peak. Tantalum, niobium, and titanium are effective solid-solution hardeners of γ' at room temperature. Tungsten and molybdenum are strengtheners at both room and elevated temperatures, while cobalt does not solid-solution strengthen γ' .

Gamma double prime (γ''), a bct coherent precipitate of composition Ni_3Nb , precipitates in nickel-iron-base alloys such as Inconel 706 and Inconel 718. In the absence of iron, or at temperatures and times shown in the transformation diagram of an iron-containing alloy (Fig. 4), orthorhombic precipitate of the same Ni_3Nb composition (delta phase) forms instead. The latter is invariably incoherent and does not confer strength when present in large quantities. However, small amounts of delta phase can be used to control and refine grain size, resulting in improved tensile properties, fatigue resistance, and creep rupture ductility. Careful heat treatment is required to ensure precipitation of γ' instead of δ .

Fig. 4 Transformation diagram for vacuum-melted and hot-forged Inconel 718 bar. Source: Ref 8

Gamma double prime often precipitates together with γ' in Inconel 718, but γ'' is the principal strengthening phase under such circumstances. Unlike γ' , which causes strengthening through the necessity to disorder the particles as they are sheared, γ'' strengthens by virtue of high coherency strains in the lattice. More detailed descriptions of the physical metallurgy of γ'/γ'' alloys appears in the section "Iron-Base Superalloys" in this article.

Grain-Boundary Chemistry. The improvement of creep properties by very small additions of boron and zirconium is a notable feature of nickel-base superalloys. Improved forgeability and better properties have also resulted from magnesium additions of 0.01 to 0.05% (Ref 5). It is believed that this is due primarily to the tying up of sulfur, a grain-boundary embrittler, by the magnesium.

Mechanisms for these property effects are nuclear. However, it is believed that boron and zirconium segregate to grain boundaries because of their large size misfit with nickel. Because, at higher temperatures, cracks in superalloys usually propagate along grain boundaries, the importance of grain-boundary chemistry is apparent. Although early work on coarse-grain materials suggested that boron and zirconium influence rupture properties because of their effects on carbide and γ' distribution, recent work on P/M superalloys has revealed no such effects with ultrafine grain size.

Boron and zirconium also improve the rupture life of γ' -free alloys, cobalt alloys, and stainless steels, so that microstructural alterations cannot, in any case, apply to all systems. Boron may also reduce carbide precipitation at grain boundaries by releasing carbon into the grains. Magnesium may have a similar effect in a nickel-chromium-titanium-aluminum alloy in which intergranular MC has been noted (Ref 5). Finally, the segregation of misfitting atoms to grain boundaries may reduce grain-boundary diffusion rates. Direct evidence of a lowering of grain-boundary diffusivity by 0.11% Zr in Ni-20% Cr alloys over the range of 800 to 1200 K has recently been reported (Ref 10). This effect was accompanied by the precipitation of several precipitates containing zirconium at grain boundaries. The creep strength increased significantly, and the fracture mode changed from intergranular to transgranular ductile rupture, with a corresponding substantial increase in ductility.

Carbides in superalloys serve a number of functions. They often precipitate at grain boundaries in nickel alloys, whereas in cobalt and iron superalloys, intergranular sites are common. Early work suggested that some grain-boundary carbides were detrimental to ductility, but most investigators now believe that discrete carbides (as well as magnesium) exert a beneficial effect on rupture strength at high temperatures.

Carbide Types and Typical Morphologies. The common nickel-base alloy carbides are MC, $M_{23}C_6$, and M_6C . MC usually exhibits a coarse, random, cubic (Fig. 5a), or script morphology. The carbide $M_{23}C_6$ is found primarily at grain boundaries (Fig. 5b) and usually occurs as irregular, discontinuous, blocky particles, although plates and regular geometric forms have been observed. The M_6C carbides also can precipitate in blocky form in grain boundaries and less

often in a Widmanstätten intragranular morphology. Although data are sparse, it appears that continuous grain-boundary $M_{23}C_6$ and Widmanstätten M_6C , caused by an improper choice of processing or heat-treatment temperatures, are to be avoided for best ductility and rupture life.

Fig. 5 Udimet 700 nickel-base heat-resistant alloy. (a) Udimet 700 solution annealed at 1177 °C (2150 °F) for 4 to 6 h and then aged 5000 h at 760 °C (1400 °F). Replica electron micrograph shows large particle of MC at grain-boundary intersection and γ' in grains of γ matrix. 4500 \times . (b) Udimet 700 solution annealed as for (a) and aged for 5000 h at 815 °C (1500 °F). Replica electron micrograph shows acicular sigma, carbide ($M_{23}C_6$) at grain boundary, and γ' within grains of the γ matrix. 4700 \times . Source: Ref 9

MC carbides, fcc in structure, usually form in superalloys during freezing. They are distributed heterogeneously through the alloy, both in intergranular and transgranular positions, often interdendritically. Little or no orientation relation with the alloy matrix has been noted. MC carbides are a major source of carbon for subsequent phase reactions during heat treatment and service (Ref 5). In some alloys, such as Incoloy 901 and A286, MC films may form along grain boundaries and reduce ductility.

These carbides, for example, TiC and HfC, are among the most stable compounds in nature. The preferred order of formation (in order of decreasing stability) in superalloys for these carbides is HfC, TaC, NbC, and TiC. This order is not the same as that of thermodynamic stability, which is HfC, TiC, TaC, and NbC. In these carbides, M atoms can readily substitute for each other, as in (Ti, Nb)C. However, the less reactive elements, principally molybdenum and tungsten, can also substitute in these carbides. For example, (Ti,Mo)C is found in Udimet 500, M-252, and René 77. It appears that the change in stability order cited above is due to the molybdenum or tungsten substitution, which weakens the binding forces in MC carbides to such an extent that degeneration reactions, discussed later, can occur. This typically leads to the formation of the more stable compounds $M_{23}C_6$ - and M_6C -type carbides in the alloys during processing or after heat treatment and/or service. Additions of niobium and tantalum tend to counteract this effect. Recent alloys with high niobium and tantalum contents contain MC carbides that do not break down easily during processing or solution treatment in the range of 1200 to 1260 °C (2190 to 2300 °F).

The carbides $M_{23}C_6$ readily form in alloys with moderate to high chromium content. They form during lower-temperature heat treatment and service (that is, 760 to 980 °C, or 1400 to 1800 °F) both from the degeneration of MC carbide and from soluble residual carbon in the alloy matrix. Although usually seen at grain boundaries, they occasionally occur along twin bands, stacking faults, and at twin ends. The carbides $M_{23}C_6$ have a complex cubic structure, which, if the carbon atoms were removed, would closely approximate the structure of the TCP σ phase. In fact, σ plates often nucleate on $M_{23}C_6$ particles.

When tungsten or molybdenum is present, the approximate composition of $M_{23}C_6$ is $Cr_{21}(Mo,W)_2C_6$, although it also has been shown that appreciable nickel can substitute in the carbide. It is also possible for small amounts of cobalt or iron to substitute for chromium.

The $M_{23}C_6$ particles strongly influence the properties of nickel alloys. Rupture strength is improved by the presence of discrete particles, apparently through the inhibition of grain-boundary sliding. Eventually, however, failure can initiate either by fracture of particles or by decohesion of the carbide/matrix interface. In some alloys, cellular structures of $M_{23}C_6$ have been noted. These can cause premature failures, but can be avoided by proper processing and/or heat treatment.

The M_6C carbides have a complex cubic structure. They form when the molybdenum and/or tungsten content is more than 6 to 8 at.%, typically in the range of 815 to 980 °C (1500 to 1800 °F). The M_6C forms with $M_{23}C_6$ in René 80, René

41, and AF 1753. Typical formulas for M_6C are $(Ni,Co)_3Mo_3C$ and $(Ni,Co)_2W_4C$, although a wider range of compositions has been reported for Hastelloy X. Therefore, M_6C carbides are formed when molybdenum or tungsten acts to replace chromium in other carbides; unlike the more rigid $M_{23}C_6$, the compositions can vary widely. Because M_6C carbides are stable at higher levels than are $M_{23}C_6$ carbides, M_6C is more commercially important as a grain-boundary precipitate for controlling grain size during the processing of wrought alloys.

Carbide Reactions. MC carbides are a major source of carbon in most nickel-base superalloys below 980 °C (1800 °F). However, MC decomposes slowly during heat treatment and service, releasing carbon for several important reactions.

The principal carbide reaction in many alloys is believed to be the formation of $M_{23}C_6$ (Ref 5):

The carbide M_6C can form in a similar manner.

Also, M_6C and $M_{23}C_6$ interact, forming one from the other (Ref 4):

or

depending on the alloy. For example, René 41 and M-252 can be heat treated to generate MC and M_6C initially, with long-time exposure causing the conversion of M_6C to $M_{23}C_6$ (Ref 4).

These reactions lead to carbide precipitation in various locations, but typically at grain boundaries. Perhaps the most beneficial reaction (for high creep resistance applications), one that is controlled in many heat treatments, is that shown in Eq 1. Both the blocky carbides and the γ' produced are important in that they may inhibit grain-boundary sliding. In many cases, the γ' generated by this reaction coats the carbides, and the grain boundary becomes a relatively ductile, creep-resistant region.

Borides. Small additions of boron are essential to improved creep-rupture resistance of superalloys. Borides are hard particles, blocky to half moon in appearance, that are observed at grain boundaries. The boride found in superalloys is of the form M_3B_2 , with a tetragonal unit cell. At least two types of borides have been observed in Udimet 700; the type observed depends upon the thermal history of the alloy. These boride types are $(Mo_{0.48}Ti_{0.07}Cr_{0.39}Ni_{0.3}Co_{0.3})_3 B_2$ and $(Mo_{0.31}Ti_{0.07}Cr_{0.49}Ni_{0.08}Co_{0.07})_3 B_2$. However, when Phacomp procedures are used to estimate long-term alloy stability, the composition $(Mo_{0.5}Ti_{0.15}Cr_{0.25}Ni_{0.10})_3 B_2$ is usually assumed. Because the level of boron added rarely exceeds 0.03 wt%, and because it is often substantially less than the solubility limit of 0.01%, the volume fraction of borides tends to be quite small. In fact, direct observation has been made of boron segregation to grain boundaries in Udimet 700 containing 0.03 wt% B, but grain boundaries decorated with fine borides were difficult to find in these observations (Ref 11).

TCP Phases. In some alloys, if composition has not been carefully controlled, undesirable phases can form either during heat treatment or, more commonly, during service. These precipitates, known as TCP phases, are composed of close-packed layers of atoms parallel to $\{111\}$ planes of the γ matrix. Usually harmful, they may appear as long plates or needles, often nucleating on grain-boundary carbides. Nickel alloys are especially prone to the formation of σ and μ . The formula for σ is $(Fe,Mo)_x (Ni,Co)_y$, where x and y can vary from 1 to 7. Alloys containing a high level of body-centered cubic (bcc) transition metals (tantalum, niobium, chromium, tungsten, and molybdenum) are most susceptible to TCP formation.

The σ hardness and its platelike morphology cause premature cracking, leading to low-temperature brittle failure, although yield strength is unaffected. However, the major effect is on elevated-temperature rupture strength, as shown for

Udimet 700 in Fig. 6. Sigma formation must deplete refractory metals in the γ matrix, causing loss of strength of the matrix. Also, high-temperature fracture can occur along σ plates rather than along the normal intergranular path, resulting in sharply reduced rupture life. Platelike μ can form also, but little is known about its detrimental effects.

Fig. 6 Log stress versus log rupture life at 815 °C (1500 °F) for Udimet 700. Source: Ref 12

Heat Treatment

Wrought alloys are, first, solution treated to dissolve nearly all γ' and carbides other than the very stable MC carbides. Typical solution treatments (for creep-limited applications) are in the range of 1050 to 1200 °C (1920 to 2190 °F) (Table 3) and may be followed by a second solution treatment at lower temperature. Some γ' can form upon air cooling from the solution treatment temperature. Aging is then carried out in several steps to coarsen the γ' that is formed upon cooling, as well as to precipitate additional γ' .

A two-step aging treatment is commonly used, with the first treatment in the range of 850 to 1100 °C (1560 to 2010 °F) over a period of up to 24 h. Aging at one or more lower temperatures, for example at 760 °C (1400 °F) for 16 h, completes the precipitation of γ' . The finer γ' produced in the second aging treatment is advantageous for tensile strength as well as for rupture life. Both solution and aging anneals are followed by air cooling.

Carbide distribution also is controlled by the heat treatment schedule. Modifications to the γ' heat treatment procedure often are required to avoid problems with carbide films at grain boundaries. For example, a solution treatment of René 41 at 1175 °C (2150 °F) leads to subsequent precipitation of a grain-boundary film of $M_{23}C_6$, with deleterious effects on mechanical properties. Therefore, a lower solution treatment temperature (about 1075 °C, or 1970 °F) is used to preserve the fine-grain as-worked structure with well-dispersed M_6C (Ref 4).

Additional heat treatments may be carried out in connection with the application of diffusion or overlay coatings, although in some cases the coating treatment coincides with an aging treatment.

Alloying for Surface Stability

Low-Temperature Corrosion. High chromium contents are required in nickel-base alloys for good resistance to corrosive media such as aqueous solutions and acids at low temperatures. A series of Hastelloy and Inconel alloys has been developed for such applications. Hastelloy C and Inconel 600 are typical: the former contains 16.5% Cr and 17% Mo as principal components for corrosion resistance, while Inconel 600 contains 15.5% Cr and 8% Fe. Other Hastelloy alloys contain up to 28% Mo, sometimes with small additions of tungsten.

Oxidation and Hot Corrosion. At elevated temperatures, oxidation resistance is provided by Al_2O_3 or Cr_2O_3 protective films. Accordingly, nickel-base alloys must contain one or both of these elements even where strength is not a principal factor. For example, Hastelloy X, one of the most oxidation and (hot) corrosion resistant of all nickel-base alloys, contains 22% Cr, 9% Mo, and 18.5% Fe as principal solutes (Table 1). Because Hastelloy X is essentially a solid-

solution alloy when placed into service (carbides precipitate after long-term exposure), the alloy is much weaker than superalloys containing γ' or γ'' as strengthening precipitates.

Because chromium is known to degrade the high-temperature strength of γ' (see Fig. 3), there has been a strong incentive to lower chromium content in modern super-alloys. Thus, the level of chromium decreased from 20% in earlier wrought alloys to as little as 9% in modern cast alloys. Unfortunately, this compositional change degraded hot corrosion resistance to the point that superalloys used in gas turbines had to be coated.

Further, as turbine blade temperatures exceed 1000 °C (1830 °F), Cr_2O_3 tends to decompose to CrO_3 , which is more volatile and therefore less protective. To some extent, the loss of oxidation resistance has been compensated for by raising aluminum contents, although aluminum resides primarily in γ' . (Aluminum in small quantities promotes the formation of Cr_2O_3 .) However, Al_2O_3 is less protective than Cr_2O_3 under sulfidizing conditions, making coatings indispensable in aircraft turbines and, more recently, in industrial turbines.

Other elements that contribute to oxidation and hot corrosion resistance are tantalum, yttrium, and lanthanum. The rare earths appear to improve oxidation resistance by preventing spalling of the oxide, while the mechanism for improvement with tantalum is not known. Yttrium is now widely used in overlay coatings of the NiCrAlY type.

Finally, it must be pointed out that molybdenum and tungsten are considered to be the most deleterious solutes in terms of hot corrosion resistance. Nevertheless, one or both of these elements are required for strength (for example, most of the γ' -strengthened alloys in Tables 1 and 9), so that alloying for improved surface stability is often in conflict with alloying for strength. The two most prominent solutes that provide both strength and surface stability are aluminum and tantalum.

Protection Against Oxidation and Corrosion. Superalloys are often diffusion or overlay coated in order to improve their corrosion resistance. The overlay coatings used are based on iron-chromium-aluminum-yttrium, cobalt-chromium-aluminum-yttrium, and nickel-chromium-aluminum-yttrium alloys. The earlier, less protective diffusion coatings are based on the reaction of aluminum with the substrate to form one or more aluminum-rich intermetallics (NiAl and/or Ni_2Al_3).

An important consideration for coated superalloys is the reduction in incipient melting temperature of the system (coating/base metal) that may result from the change in composition caused by the diffusion of coating components inward from the surface. Incipient melting (Table 4) reduces grain-boundary strength and ductility and thus reduces stress-rupture capabilities. Once an alloy has been heated above its incipient melting point, the alloy properties cannot be restored by heat treatment. Generally, a cast alloy should not be used for a structural application at any temperature higher than the point about 125 °C (225 °F) below its incipient melting temperature. Oxidation behavior and strength will determine how close actual metal temperatures may approach this suggested upper limit. Wrought alloys are used for applications, such as turbine disks and rotating seals, that typically operate at much lower temperatures. Therefore, coatings are much less likely to be used for such applications.

Source: Ref 3

An important difference between nickel- and cobalt-base superalloys is related to the superior hot corrosion resistance claimed for cobalt-base alloys in atmospheres containing sulfur, sodium salts, halides, vanadium oxides, and lead oxide, all of which can be found in fuel-burning systems. In part, this apparent superiority may arise from the higher chromium content characteristic of cobalt-base alloys. Nickel forms low melting point eutectics with nickel sulfide; in sulfur-bearing gases, the attack on nickel alloys may be devastating. Generalizations about the comparative oxidation and hot corrosion resistance of nickel- and cobalt-base alloys must be treated with some caution because resistance to corrosion varies widely within each alloy group. Small variations in service conditions (temperature, fuel impurity content, gas flow rates) can sharply alter results.

Property Data

Mechanical and physical properties for nickel-, iron-, and cobalt-base wrought superalloys are defined in the tables and graphs briefly described here. Although much data are presented comprehensively in this section, descriptions of iron- and cobalt-base superalloys are provided independently in respective sections, along with representative data. Ultimate tensile strength values at a variety of temperatures are given in Table 5, while tensile yield strengths and elongations are provided in Table 6. Rupture strengths measured at 1000 h are given in Table 7, while stress-rupture curves for selected superalloys are shown in Fig 7(a), 7(b) and 8. Physical properties of wrought superalloys are given in Table 8.

Iron-Base Superalloys

Microstructure. Irons-base superalloys evolved from austenitic stainless steels and are based on the principle of combining a closed-packed fcc matrix with (in most cases) both solid-solution hardening and precipitate-forming elements. The austenitic matrix is based on nickel and iron, with at least 25% Ni needed to stabilize the fcc phase. Other alloying elements, such as chromium, partition primarily to the austenite for solid-solution hardening. The strengthening precipitates are primarily ordered intermetallics, such as γ' Ni₃Al, γ Ni₃Ti, and γ'' Ni₃Nb, although carbides and carbonitrides may also be present. Elements that partition to grain boundaries, such as boron and zirconium, perform a function similar to that which occurs in nickel-base alloys; that is, grain-boundary fracture is suppressed under creep rupture conditions, resulting in significant increases in rupture life. Compositions of wrought iron-nickel alloys are listed in Table 9. A summary of the function of various alloying elements is found in Table 2.

(e) Ref 3

Several groupings of iron-nickel alloys based on composition and strengthening mechanisms have been established. Alloys that are strengthened by ordered fcc γ' , such as V-57 and A-286, and contain 25 to 35 wt% Ni, represent one subgroup. The γ' phase is titanium-rich in these alloys, and care must be taken to avoid an excessively high titanium-to-aluminum ratio, resulting in the replacement of fcc γ' by hexagonal close-packed (hcp) $\gamma(\text{Ni}_3\text{Ti})$, a less effective strengthener.

A second iron-rich subgroup, of which Inconel X750 and Incoloy 901 are examples, contains at least 40% Ni, as well as higher levels of solid-solution strengthening and precipitate-forming elements.

Another iron-rich group, based on the iron-nickel-cobalt system strengthened by fcc γ' , combines low thermal expansion coefficients and relatively high strength to a temperature of 650 °C (1200 °F). These alloys are typified by Incoloy 903, 907, 909, Pyromet CTX-1, and Pyromet CTX-3, which do not have any chromium and oxidize and spall readily. The unusually low thermal expansion coefficient results from the elimination of ferrite-stabilizing elements. In each of these alloys, a small quantity of titanium is present to allow the formation of metastable $\gamma'(\text{Ni}_3\text{Ti},\text{Al})$ in the austenite matrix during aging. Another phase that may occur after extended aging of the Pyromet alloys is $\eta(\text{Ni}_3\text{Ti})$, a plate-like, stable hcp phase that contributes less to strengthening than does γ' . The alloys are used for shafts, rings, and casings to permit the reduction of clearances between rotating and static components.

Alloys With High Nickel Content. Two important classes of iron-nickel alloys actually contain more nickel than iron. The first group, typified by Incoloy 706 and Inconel 718 (Table 1), are strengthened by a coherent bcc phase known as $\gamma''(\text{Ni}_3\text{Nb})$. These alloys contain 3 and 5 wt% Nb, respectively. The iron acts principally as a catalyst for the formation of γ'' which is metastable. These alloys also contain smaller quantities of aluminum and titanium, thereby leading to the formation of $\gamma' \text{Ni}_3\text{Al},\text{Ti}$. Improper heat treatment can lead to the formation of a stable orthorhombic δ phase with the composition Ni_3Nb . Because proper heat treatment procedures are essential for these alloys, time-temperature-transformation diagrams such as that shown in Fig. 4 are used to establish appropriate heat treatment schedules.

The maximum-use temperature of Inconel 718 is about 650 °C (1200 °F) because of instability of the γ'' precipitate. Other problems that have arisen with this alloy are notch sensitivity from about 525 to 750 °C (975 to 1380 °F) when tested in air (generally caused by improper processing) and a significantly higher rate of crack growth in air than in vacuum. Recent work has shown that lowering the carbon content can result in equal or better properties than those of standard Inconel 718 (Ref 17). Further, increasing the aluminum and niobium content and the aluminum-to-titanium ratio in Inconel 718 enhances its mechanical properties by producing more of the stable γ' phase and less of the undesirable δ phase (Ref 18).

A second of nickel-rich alloys displays little or no precipitation strengthening. However, second phases may be seen after long-term exposure. Alloys in this group include Hastelloy X and N-155.

Boron in quantities of 0.003 to 0.03 wt% and, less frequently, small additions of zirconium are added to improve stress-rupture properties and hot workability. Zirconium also forms the MC carbide ZrC . Another MC carbide, NbC , is found in alloys that contain niobium, such as Inconel 706 and Inconel 718. Vanadium also is added in small quantities to iron-nickel alloys to improve both notch ductility at service temperatures and hot workability. Manganese and rare earth elements may be present as deoxidizers; rare earths also have been added to Hastelloy X to improve oxidation resistance.

Generally, the iron-nickel alloys described above have useful strengths to about 650 °C (1200 °F). Inconel 718 is one of the strongest (at low temperatures) and most widely used of all superalloys, but it rapidly loses strength in the range of 650 to 815 °C (1200 to 1500 °F). Figures 9 and 10 show creep strength and yield strength, respectively. This is probably due to the high lattice misfit associated with the precipitation of γ'' in the austenitic matrix.

Fig. 9 1000-h creep rupture strength of turbine rotor and compressor blade alloys. Source: Ref 14

Fig. 10 Yield strength at 0.2% offset of five candidate compressor blade alloys compared with that of 12Cr-0.6Mo steel. Source: Ref 14

The carbide and carbonitride strengthened alloys have useful strength to at least 815 °C (1500 °F). Hastelloy X, a very weak alloy at all temperatures, is widely used as a combustion chamber liner, operating at temperatures in excess of 1050

°C (1920 °F) because of its oxidation resistance (Fig. 11). Other physical and mechanical properties are given in Tables 5, 6, 7, 8, and Fig. 7(a) , 7(b), and 8.

Fig. 11 Cyclic oxidation resistance of a range of superalloys. Thermal cycle was between room temperature and 1000 °C (1830 °F) (except for Inconel 601 and 617); 15 min heating, 5 min cooling. For Inconel alloys 601 and 617, cycle was between room temperature and 1095 °C (2000 °F). Source: Ref 14

Wrought and P/M Superalloys

N.S. Stoloff, Rensselaer Polytechnic Institute

Cobalt-Base Superalloys

Wrought cobalt-base alloys, unlike other superalloys, are not strengthened by a coherent, ordered precipitate. Rather, they are characterized by a solid solution strengthened austenitic (fcc) matrix in which a small quantity of carbides is distributed. (Cast cobalt alloys rely upon carbide strengthening to a much greater extent.) Cobalt crystallizes in the hcp structure below 417 °C (780 °F). At higher temperatures, it transforms to fcc. To avoid this transformation during service, virtually all cobalt-base alloys are alloyed with nickel in order to stabilize the fcc structure between room temperature and the melting point.

Melting point is not a reliable guide to the temperature capability of iron-, nickel-, and cobalt-base superalloys. Although nickel possesses the lowest melting point of the three alloy bases, it has by far the highest temperature capability under moderate-to-high stresses. Further, incipient melting temperatures of nickel- and cobalt-base alloys are very similar (see Table 4). Cobalt-base alloys, with a flatter rupture stress-temperature relationship, may actually display better creep rupture properties above about 1000 °C (1830 °F) than the other superalloys. This may best be seen by means of comparative Larson-Miller plots for superalloys (Fig. 12). Also, cobalt-base alloys display superior hot corrosion resistance at high temperatures, probably a consequence of the considerably higher chromium contents that are characteristic of these alloys. A list of wrought cobalt-base alloys and their compositions appears in Table 10, and the function of various solutes is summarized in Table 2.

(c) Ref 1

Fig. 12 Larson-Miller curves, used to describe the stress-rupture characteristics of an alloy over wide temperature, life, and stress ranges. For example, if an alloy selected for an application requires a minimum of 100 h of exposure of 925 °C (1700 °F) under a stress of 170 MPa (25 ksi), then the Larson-Miller formula of $P + T (20 + \log t) \times 10^3$ gives the parameter 47.5, where P = LM parameter, T = temperature, and t = time in hours. Comparing 47.5 on the abscissa with a stress of 170 MPa (25 ksi) on the ordinate, it is evident that Udimet 700 is the only alloy that falls above the required point.

Cobalt-base alloys generally exhibit better weldability and thermal-fatigue resistance than do nickel-base alloys. Another advantage of cobalt-base alloys is the capability to be melted in air or argon, in contrast to the vacuum melting required for nickel-base and iron-nickel-base alloys containing the reactive metals aluminum and titanium. However, unlike nickel-base alloys, which have a high tolerance for alloying elements in solid solution, cobalt-base alloys are more likely to precipitate undesirable platelike σ , Laves, and similar TCP phases.

Microstructure. Virtually all cobalt alloys are based on an fcc matrix obtained by alloying with 10% or more nickel. Iron, manganese, and carbon additions also stabilize the fcc phase, while nickel and iron additions improve workability. Exerting the opposite hcp stabilizing tendency are other common alloying elements, such as tungsten, added primarily for

solid-solution strengthening, as in L-605, and chromium, added primarily for oxidation and hot corrosion resistance. Tungsten is favored over molybdenum as a strengthener, even though the latter is more effective per atomic because tungsten, alone among potential solutes in cobalt, raises the melting temperature of cobalt. Tantalum has been used as a replacement for tungsten in sheet alloys MAR-M 918 and S-57, while molybdenum contents of up to 10 wt% are found in the work-hardened Multiphase (MP) alloys.

Improved oxidation and corrosion resistance with 5 wt% Al have been noted in a few cobalt-base alloys (Ref 19). Titanium additions also have been made in order to precipitate coherent, ordered Co_3Ti as a strengthening phase. Unfortunately, this phase is stable only to about 700 °C (1290 °F), which is much lower than for γ' Ni_3Al , Ti in Ni-base alloys.

Increased susceptibility to Laves-phase precipitation has been noted in the presence of silicon in tungsten-containing alloys such as L-605. Haynes 188 was developed with reduced tungsten, increased nickel, and controlled silicon contents in order to avoid this problem.

As in the case of nickel-base alloys, a variety of carbides have been found in cobalt alloys. These include M_{23}C_6 , M_6C , and MC carbides. In both L-605 and Haynes 188, M_6C transforms into M_{23}C_6 during exposure to temperatures in the range of 816 to 927 °C (1500 to 1700 °F) for 3000 h. MC carbides are found only in alloys containing tantalum, niobium, zirconium, titanium, or hafnium. Among wrought cobalt-base alloys, MAR-M 918 contains tantalum, while CM-7, a Belgian modification of L-605, contains a small amount of aluminum and titanium. Therefore, these two alloys will display MC carbides.

In addition to carbides, small quantities of intermetallic phases such as Co_3W , Co_2W , and Co_7W_6 have been found in L-605. Other alloys display the compounds CoAl , Co_3Ti , and $\text{Co}_2(\text{Ta,Nb,Ti})$. However, it is unlikely that these phases contribute to the strengthening of the γ matrix. On the contrary, Co_7W_6 and $\text{Co}_2(\text{Ta,Nb,Ti})$ are TCP phases that are likely to cause the deterioration of mechanical properties. A uniform dispersion of $\text{Co}_3(\text{Ti,Al})$ has been achieved in CM-7 by solution treatment at 1200 °C (2190 °F) and aging at 800 °C (1470 °F). However, this microstructure is unstable at temperatures of 815 °C (1500 °F) and above for times over 1000 h. Figure 13 shows the distribution of phases after various heat treatments for two age-hardened cobalt-base alloys, Haynes 25 and Haynes 188.

Fig. 13 Microstructures of Haynes 25 and 188 after various heat treatments. (a) Haynes 25, solution annealed at 1204 °C (2200 °F) and aged for 3400 h at 816 °C (1500 °F). Structure is made up of precipitates of M_6C and Co_2W intermetallic compound in an fcc matrix. (b) Haynes 25, solution annealed at 1204 °C (2200 °F) and aged for 3400 h at 871 °C (1600 °F). Structure is same as (a). (c) Haynes 25, solution annealed at 1204 °C (2200 °F) and aged for 3400 h at 927 °C (1700 °F). Structure is same as (a), but M_6C is considered primary, while

Co₂W is considered secondary. (d) Haynes 188, cold rolled, 20% solution annealed at 1177 °C (2150 °F) for 10 min before water quenching. Fully annealed structure is M₆C particles in an fcc matrix. (e) Haynes 188, solution annealed at 1177 °C (2150 °F) and aged at 649 °C (1200 °F) for 3400 h. Microstructure is particles of M₆C and M₂₃C₆ in an fcc matrix. (f) Haynes 188, solution annealed at 1177 °C (2150 °F) and aged 871 °C (1600 °F) for 6244 h. Structure is M₂₃C₆, Laves phase, and probably M₆C in an fcc matrix. All 500×

An additional source of strengthening, in the Multiphase alloys, arises from the strain-induced transformation of the γ matrix to an hcp structure. This transformation is closely linked to the occurrence of stacking faults in cobalt-base alloys. The lower the stacking fault energy of the γ matrix (as in low nickel, high refractory element content alloys), the more readily will faulting occur.

Applications and Properties. Various wrought cobalt-base alloys can be grouped according to use:

- Alloys for use primarily at high temperatures from 650 to 1150 °C (1200 to 2100 °F), including S-816, Haynes 25, Haynes 188, Haynes 556, and UMC0-50
- Fastener alloys MP35N and MP159, for use for about 650 °C (1200 °F)
- Wear-resistant Stellite 6B

All alloys in the heat-treated and softened condition have fcc crystal structures. However, alloys MP35N and MP159 develop controlled amounts of close-packed hexagonal (cph) structure during the thermomechanical processing recommended before service applications, which are typically used as fasteners for service to 650 °C (1200 °F). Stellite 6B, when heat treated between 650 and 1060 °C (1200 and 1900 °F), and Haynes 25, when exposed for 1000 h or more at temperatures near 650 °C (1200 °F), may partly transform to a cph structure.

None of the cobalt-base superalloys are complete solid-solution alloys because all contain secondary phases in the form of carbides (M₆C, M₂₃C₆, M₇C₃, or MC) or intermetallic compounds. Aging causes additional second-phase precipitation, which generally results in some loss of room-temperature ductility (refer to Fig. 11). Of the high-temperature group, alloy S-816 originally was used extensively in turbo-chargers, as well as gas turbine wheels, blades, and vanes, but has been largely replaced by higher-strength, lower-density nickel-base alloys with improved resistance to adverse environments.

Haynes 25 is perhaps the best-known wrought cobalt-base alloy and has been widely used for hot sections of gas turbines; components of nuclear reactors; devices for surgical implants; and, in the cold-worked condition, for fasteners and wear pads.

Haynes 188 is an alloy that was specially designed for sheet-metal components, such as combustors and transition ducts, in gas turbines. The basic composition, provided that lanthanum, silicon, aluminum, and manganese contents are judiciously controlled, provides excellent qualities, such as oxidation resistance at temperatures up to 1100 °C (2000 °F), hot corrosion resistance, creep resistance, room-temperature formability, and ductility after long-term aging at service temperatures.

Figure 14 compares the static oxidation resistance of Haynes 188 with that of several other alloys. It should be noted that Haynes 188 has excelled oxidation resistance in dry air (Fig. 14a), but displays inferior properties in moist air (Fig. 14b). Haynes 188, like Haynes 25, MP35N, and MP159, can be work hardened to relatively high hardness and tensile strength; after 50% cold reduction, Haynes 188 has a tensile strength of 1690 MPa (245 ksi) at room temperature and 1585 MPa (230 ksi) at 540 °C (1000 °F).

Fig. 14 Oxidation resistance. (a) In dry air for Haynes 188 versus Hastelloy X and L-605 alloys showing continuous penetration from original thickness. (b) Static values at 1100 °C (2010 °F) in air with 5% water vapor

UMCo-50, which contains about 21% iron, is not as strong as Haynes 25 or 188. It is not used extensively in the United States, and especially not in gas turbine applications. In Europe, on the other hand, it is used extensively for furnace parts and fixtures.

The last type of wrought cobalt alloy consists of a single alloy, Stellite 6B, which is characterized by high hot hardness and relatively good resistance to oxidation. The latter property is derived chiefly from its high chromium content (about 30%), whereas its hot hardness property is obtained through the formation of complex carbides of the Cr_7Co_3 and M_{23}C_6 types. Stellite 6B is widely used for erosion shields in steam turbines, for wear pads in gas turbines, and for bends in tube systems carrying particulate matter at high temperatures and high velocities.

Several cobalt casting alloys have been successfully prepared as powder product. Both X-40 and MAR-M 509 have exhibited superior mechanical properties under some circumstances, due either to effects of grain size or to carbide size and distribution. Property data and corresponding information on a family of cobalt-chromium-tungsten-carbon alloys that use P/M processing are provided in an appendix to this article. Powder processing also has been used to prepare oxide dispersion strengthened cobalt alloys with improved creep rupture strengths, but no commercial alloys have yet been developed.

Oxidation and Hot Corrosion. The influence of solute elements on the oxidation of cobalt-base alloys has been summarized by Sims (Ref 19) and Beltran (Ref 20) (see Table 11). Among refractory metals, only tantalum is considered beneficial, but tantalum is not added to wrought alloys. Tungsten, molybdenum, vanadium, and niobium are decidedly harmful. Caution must be exercised because carbide distribution may also play a role in oxidation resistance. Beltran (Ref 20) has suggested that the same refractory metals that degrade oxidation resistance play a similar role in hot corrosion. Niobium is cited as being harmful to both the oxidation and corrosion resistance of W-52, a cast alloy, but less so for wrought S-816, even though the latter contains twice the niobium content.

Table 11 Oxidation role of alloying additions to cobalt-base materials

Alloying element	Probable effect of addition on the oxidation behavior of a Co(20-30)Cr base
Titanium	Innocuous at low levels
Zirconium	Innocuous at low levels
Carbon	Slightly deleterious; ties up chromium
Vanadium	Harmful, even at 0.5%
Niobium	Harmful, even at 0.5%
Tantalum	Beneficial to moderate levels (<5%)
Molybdenum	Harmful; forms volatile oxides
Tungsten	Innocuous below ~1000 °C (1800 °F); harmful >1000 °C (1800 °F); forms volatile oxides
Yttrium	Beneficial; improves scale adherence
Nickel	May be slightly deleterious
Manganese	Beneficial; induces the formation of spinels
Iron	Tends to induce spinel formation

Source: Ref 19

Pettit and Giggins (Ref 21) note that cobalt and cobalt-aluminum alloys with chromium and aluminum contents below the level needed to form external scales of Cr_2O_3 or Al_2O_3 are susceptible to a form of catastrophic hot corrosion known as basic fluxing. This type of attack is inhibited by higher levels of chromium or aluminum. In general, cobalt-chromium alloys are less susceptible than nickel-aluminum and nickel-aluminum-*X* alloys, where *X* = Mo, W, or V, to two other forms of hot corrosion: alloy-induced acidic degradation and sulfur-induced degradation.

Wrought and P/M Superalloys

N.S. Stoloff, Rensselaer Polytechnic Institute

Melting and Consolidation of Wrought Alloys

Superalloy ingots must be melted and cast with due regard for the volatility and reactivity of the elements present. Vacuum melting processes are a necessity for many nickel- and iron-nickel-base alloys because of the presence of aluminum and titanium as solutes. Cobalt-base alloys, on the other hand, do not usually contain these elements and, therefore, may be melted in air.

Melt Processes (Ref 22)

Superalloy melt processes must effectively consolidate raw materials into a product that meets chemistry specifications, mechanical property requirements, microstructure and macrostructure standards, and ultrasonic inspection requirements. The traditional processes used to produce superalloy components are identified in Fig. 15. Of these processes, vacuum induction melting (VIM), vacuum arc remelting (VAR), and electroslag remelting (ESR) are briefly described below; additional details are provided in Ref 22 and in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Both the thermomechanical and powder metallurgy processes shown in Fig. 15 are described in more detail within this article in the sections "Thermomechanical Processing" and "P/M Alloys." Investment castings, as mentioned earlier, are discussed in the articles "Polycrystalline Cast Superalloys" and "Directionally Solidified and Single-Crystal Superalloys" in this Volume.

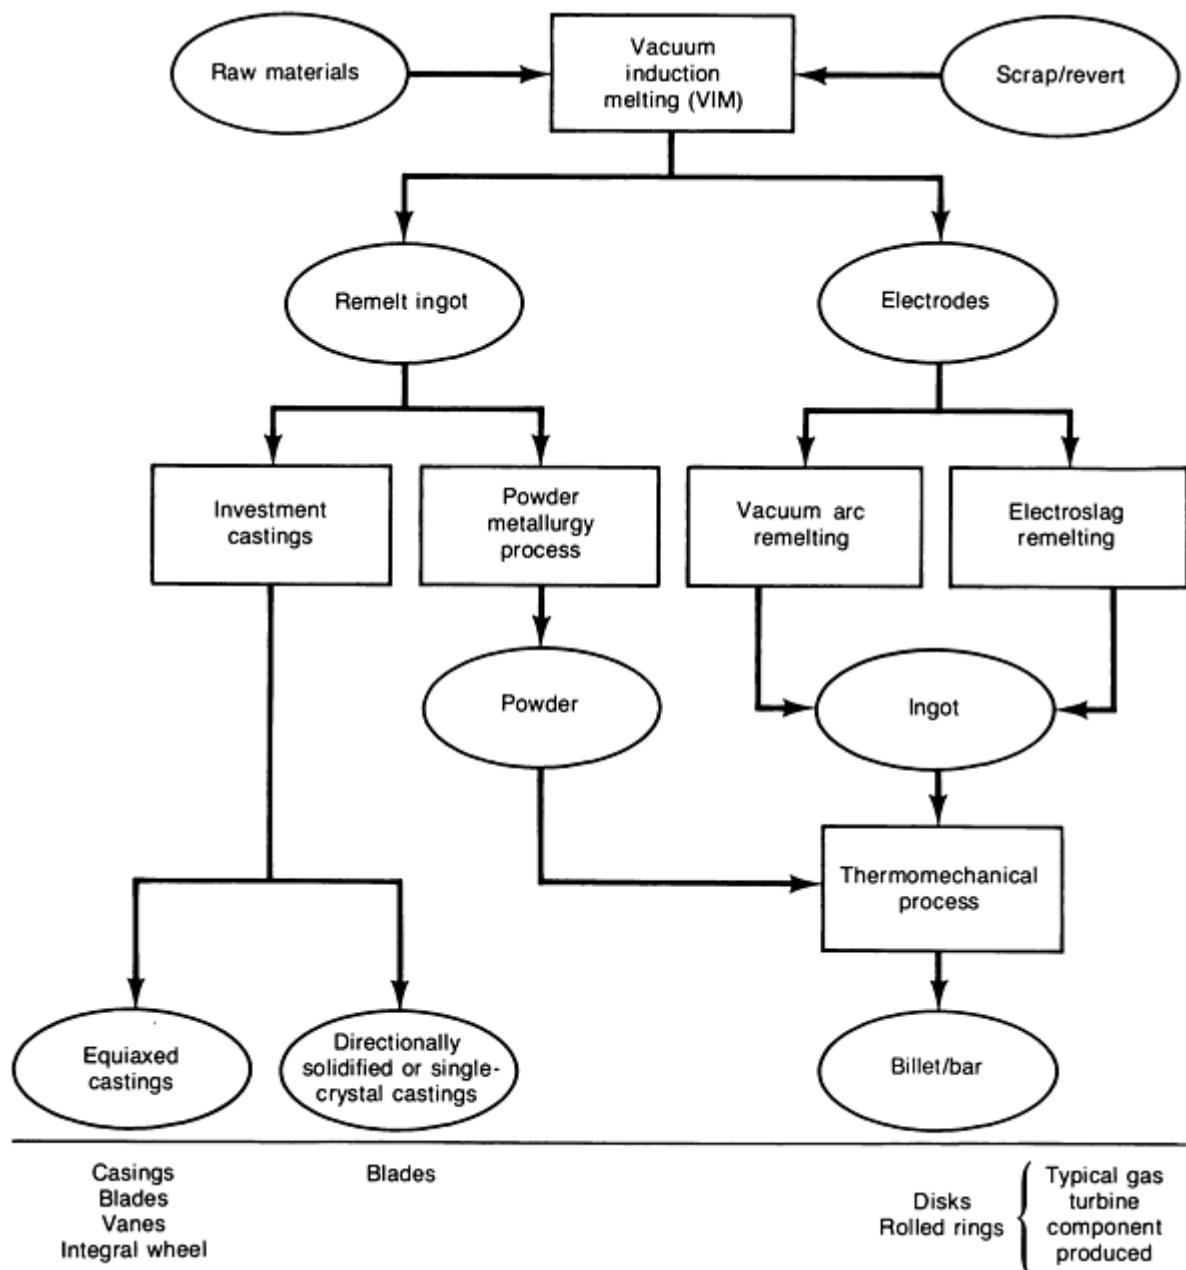

Fig. 15 Flow diagram of processes widely used to produce superalloy components. Source: Ref 22

The VIM process produces liquid metal under vacuum in an induction-heated crucible. It is used as a primary melting step in the route to producing wrought and cast products, as well as near-net shape. Before being melted, the raw material can be refined and purified and its composition can be controlled. Vacuum induction melting has been widely used in the manufacture of superalloys, which must be melted under vacuum or in an inert gas atmosphere because of their reactivity with atmospheric oxygen and nitrogen. A recent development, the installation of programmable control, in combination with a process computer for automation, allows better melt reproducibility and the capability to meet cleanliness and homogeneity demands.

The VAR process, a secondary melting technique, converts VIM-processed electrodes into ingots whose chemical and physical homogeneity have been significantly improved. In this process, a stub is welded to one end of an electrode, which is then suspended over a water-cooled copper crucible. Next, an arc is struck between the end of the electrode and the crucible bottom. Maintaining the arc generates the heat required to melt the electrode, which drips into the crucible and can subsequently be poured into molds. Many inclusions can be removed by flotation or chemical and physical processes before the molten material solidifies.

The ESR process, another secondary melting technique, may appear to be similar to the VAR process, but there are a number of differences. Remelting does not occur by striking an arc under vacuum. Instead, an ingot is built up in a water-cooled mold by melting a consumable electrode that is immersed in a slag, which is superheated by means of resistance heating. Rather than operating in a vacuum, the process is conducted in air under the molten slag. During melting, metal droplets fall through the molten slag, and chemical reactions reduce sulfur and nonmetallic inclusions. Both ESR and VAR processes allow directional solidification of an ingot from bottom to top, yielding high density and homogeneity in its macrostructure, as well as an absence of segregation and shrinkage cavities.

Future Options. Modifications of existing processes and the development of alternatives in an effort to provide cleaner and more uniform microstructures are ongoing. Future options in processing sequences may involve argon/oxygen degassing prior to vacuum induction melting in the primary melting step. Secondary melting techniques may include electron beam cold hearth refining and plasma cold hearth refining, in addition to VAR and ESR techniques. The electron beam technique appears promising because it is refractoryless, has demonstrated an ability to remove oxides, and offers a greater degree of process control. Triple melting alternatives may be represented by the VAR and vacuum arc double electrode remelt (VADER) processes. The latter is unique because the semicontinuous process can accept ultraclean electrodes and process the material in a refractoryless environment. Excellent descriptions of these options are provided in Ref 22.

Alloy Types Versus Melt Process. The austenitic high-nickel alloys and nickel-base solid-solution alloys are generally electric furnace melted. Inconels and Incolloys are electric furnace melted, followed by argon-oxygen decarburization (AOD processing). Hastelloys are generally electric furnace melted and then electroslag remelted, although vacuum induction melting followed by electroslag remelting may also be employed. Some other alloys may be simply electric arc furnace melted.

Precipitation-hardening iron-base alloys are electric furnace or vacuum induction melted and then vacuum arc or electroslag remelted. Double vacuum induction melting may be employed when critical applications are involved. In general, vacuum melting improves cleanliness and trace element-sensitive properties such as fatigue strength, ductility, and impact strength. Its effect on tensile strength is negligible.

The precipitation-hardening nickel-base alloys are generally double vacuum induction melted and then vacuum arc or electroslag remelted. Vacuum induction melting lowers the gas content (hydrogen, nitrogen, and oxygen) and evaporates trace elements (such as lead, bismuth, cadmium, tellurium, arsenic, antimony, titanium, and selenium), the presence of which can adversely affect the mechanical properties and workability of ingots. Several of these elements, even in trace amounts, can adversely affect service life. Secondary remelting using vacuum arc and electroslag processes further refines the metal by eliminating gases, nonmetallic and metallic impurities, and inclusions. Secondary remelting also produces larger ingots of uniform composition and dense homogeneous structure. Electroslag remelting is done by arc melting under a cover of slag, and the removal of sulfur is quite easy compared to vacuum melting processes. High sulfur levels are deleterious to the workability and properties of wrought heat-resisting alloys, particularly high-nickel alloys.

Forming Processes

Wrought heat-resistant alloys are manufactured in all mill forms common to the metal industry. Iron-base, cobalt-base, and nickel-base superalloys are produced conventionally as bar, billet, extrusions, plate, sheet, strip, wire, and forgings by primary mills. Inconels and Hastelloys also are available as rod, bar, plate, sheet, strip, tube, pipe, shapes, wire, forging stock, and specialty items from secondary converters.

Cast structure is refined by a working operation known as cogging (Ref 23). In this process, hydraulic presses are used with open dies. Uniform billet structure and improved surface finish are additional objectives of this process. Initial ingot breakdown is followed by methods such as rolling, forging, or extrusion.

Sheet, bar, and ring rolling are commonly employed for secondary hot working of superalloys. Working temperature ranges for many nickel-base alloys are listed in Fig. 16. Edge cracking is a problem that is minimized by rapid handling. Forgings are used in both the turbine and compressor sections of gas tubes. Rates of die closure vary from 0.3 mm/s (0.012 in./s) for hydraulic presses to 7.5 m/s (295 in./s) for hammers. While most forging is carried out with steel tooling heated in the range of 200 to 430 °C (390 to 805 °F), isothermal forging is now widely used for near-net shape processing. Superalloy or molybdenum alloy dies are heated to the same temperature as the forging, in the range of 650 to 980 °C (1200 to 1800 °F). Isothermal forging produces a uniform microstructure while requiring less material, thereby lowering machining costs. For temperatures at which superplastic behavior of superalloys occurs, less powerful presses or

hammers and slower die closure rates can be used. The benefits outweigh the increased costs of hot die tooling for expensive input materials.

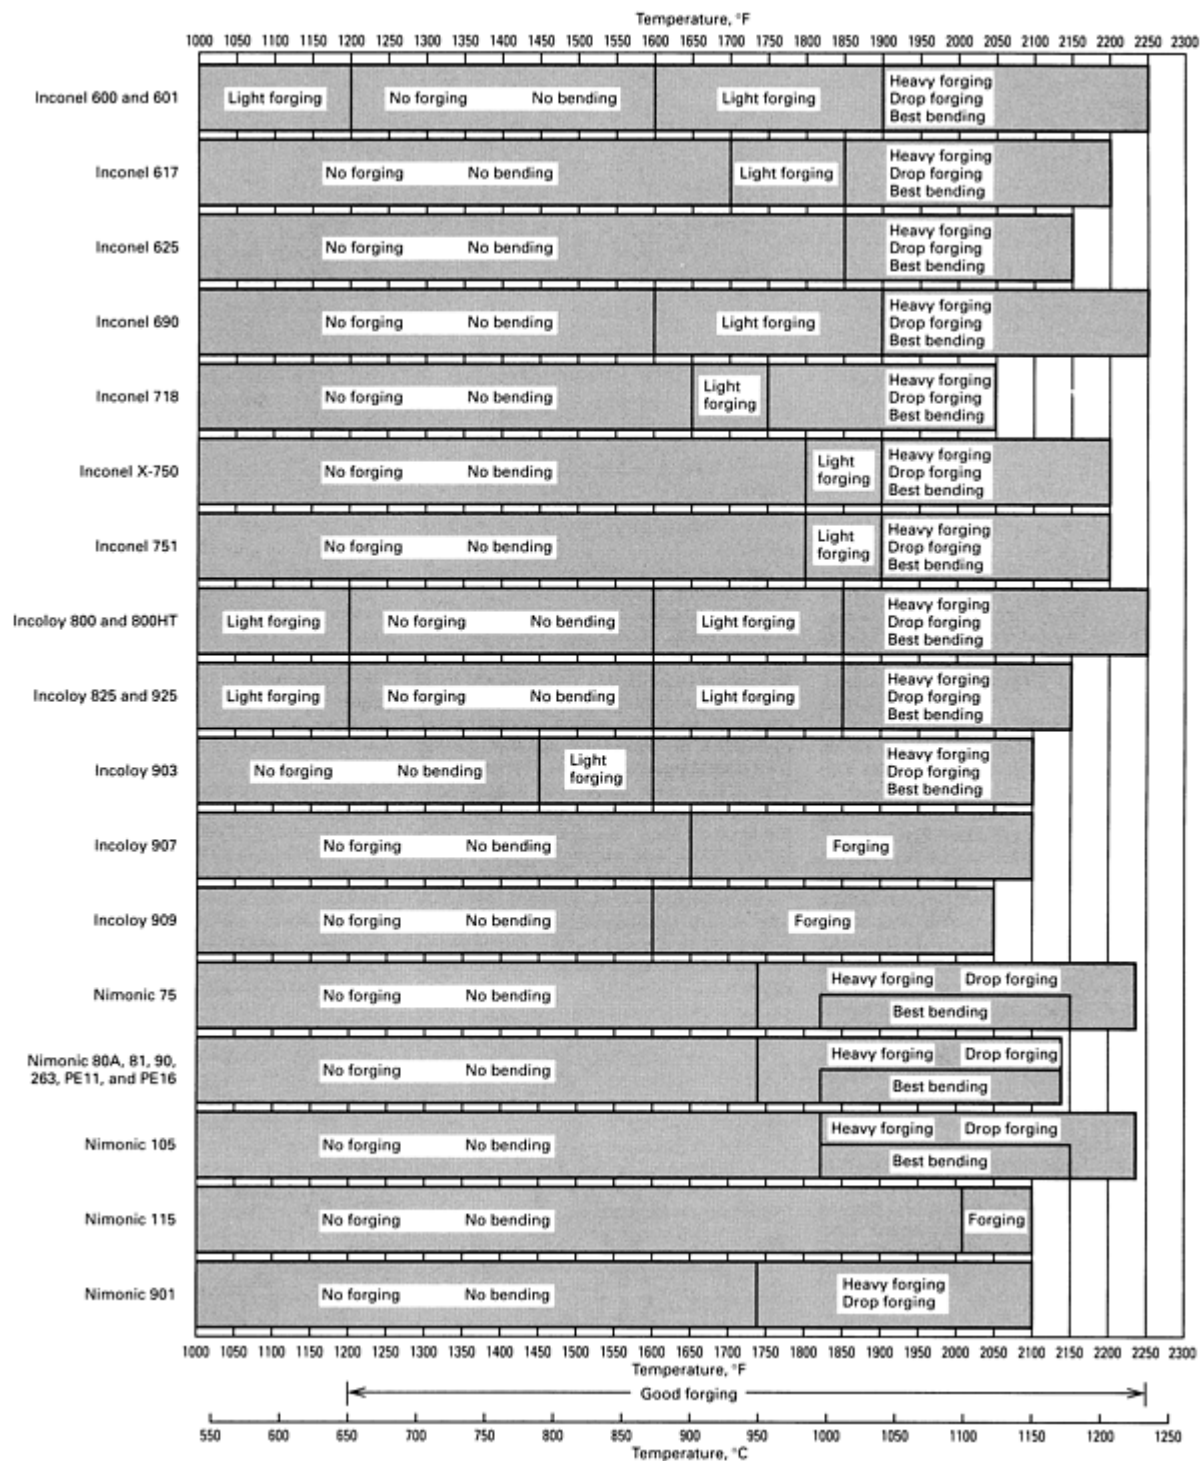

Fig. 16 Temperature ranges for the hot forming of various superalloys. Source: INCO Alloys International, Inc.

Extrusion is used for the conversion of ingot to billet, especially for the stronger, crack-prone alloys, as well as for powder-processed alloys. Canning in mild steel or stainless steel is required to avoid chilling and surface cracking. Glass is the most common lubricant (Ref 24). Seamless tubing is also produced by this method.

Sheet and other semifinished products are produced by rolling, often with many reheats, frequent conditioning, and possibly encasing of the alloy in a can. Open-die forging is carried out in flat or swaging dies. Closed-die forging is used

to produce shapes that match the impressions of dies attached to the ram and anvil. Both hammers and presses are used; for the hammers, stresses required for deformation are higher because of the higher strain rates employed.

A few superalloys can be cold formed on high-capacity equipment by drawing, extrusion, pressing and deep drawing, spinning, or rolling. For all processes except rolling, a lubricant is usually required, and speeds are relatively low. The uniform, fine-grain microstructures resulting from cold working and reannealing lead to improved mechanical properties.

Thermomechanical Processing

Grain structure may be controlled by thermomechanical processing in several iron-nickel-base alloys that have two precipitates present, the primary strengthening precipitate (γ'' Ni_3Nb in Inconel 718 and γ' Ni_3Ti in Inconel 901) and a secondary precipitate (γ in Inconel 718 and η Ni_3Ti in Inconel 901) (Ref 24, 25). The secondary precipitate is produced first, by an appropriate heat treatment (8 h at 900 °C, or 1650 °F, for 901), followed by working at about 950 °C (1740 °F), below the η solvus. Final working is carried out below the recrystallization temperature, and the alloy is subsequently recrystallized below the η solvus. Finally, the alloy is aged by standard procedures. The result is a fine-grain alloy with higher tensile strength and improved fatigue resistance.

The critical warm-working temperature range for Inconel 718 is 955 to 995 °C (1750 to 1820 °F). The upper limit avoids grain coarsening at higher temperatures due to re-solution of γ'' while the lower limit is established to avoid an excessively high flow stress during working. δ and γ'' precipitates compete for the available niobium. Therefore, any factor suppressing γ tends to favor γ'' formation, and vice versa. δ does not strengthen Inconel 718, but it reduces the room-temperature ductility. However, when some γ phase is precipitated prior to or during working, the grain size can be reduced substantially, leading to increased tensile and fatigue strength.

Other thermomechanical working schedules are used to produce a double necklace structure of fine grains surrounding the large grains formed during high-temperature recrystallization. Reductions of 25 to 50% are needed in the final working operations at 1080 to 1110 °C (1975 to 2030 °F) to produce the small recrystallized grains in cast/wrought René 95.

P/M Alloys

Aircraft gas turbine disks, designed to operate at temperatures of about 650 °C (1200 °F) in current high-performance engines, require forgeable alloys with high yield strength (to tolerate overspeed without burst), high creep resistance, and good damage tolerance. The crack growth rate must be kept low even under conditions of environmental attack and hold times under stress.

Several P/M superalloys have replaced forged alloys as turbine disks, including MERL 76, LC Astroloy, IN-100, and René 95. Table 12 gives compositions. In general, the strength of these alloys is a direct function of the γ' content. Powder processing permits the attainment of a fine grain size, which lends the alloys superplastic forming capability, as in the

Pratt and Whitney Gatorizing process. The alloys are characterized by a high homogeneous concentration of both solid-solution strengthening elements and the γ' -forming elements aluminum and titanium. These factors would limit forgeability of conventionally cast and wrought alloys.

Other P/M alloys, strengthened by a small volume percent of fine oxide particles, have been developed for turbine blade and vane applications. These alloys will be discussed in the section "Oxide Dispersion Strengthened Alloys."

The advantages of powder-processed disk alloys are:

- More uniform composition and phase distribution
- Finer grain size
- Reduced carbide segregation
- Higher material yields
- Increased flexibility in alloy design

However, several problems arise directly from powder techniques:

- Increased residual gas content
- Carbon contamination
- Ceramic inclusions
- Formation of prior particle boundary oxide and/or carbide films

These problems can lead directly to inferior mechanical properties. For example, oxide and other inclusions more readily cause crack nucleation and greater variability in fatigue life than is the case with wrought alloys. For these reasons major efforts have been made to produce a cleaner master melt and to reduce contamination during the preparation of powders. The semicontinuous carbide films on prior particle boundaries cannot be altered by simple heat treatment, but can be affected by proper hot-working schedules. These boundaries may also be minimized by the proper selection and balance of solute elements.

Powder Production. Various means of producing superalloy powders are summarized in Table 13; detailed descriptions have been published (Ref 2, 27, 28). Inert gas atomization is the most common technique (Fig. 17). An ingot is first cast, typically by vacuum induction melting, in order to minimize oxygen and nitrogen contents. In some cases remelting may be carried out by electron beam heating, arc melting under argon, or plasma heating. Atomization is carried out by pouring master melt through a refractory orifice; a high-pressure inert gas stream (typically argon) breaks up the alloy into liquid droplets, which are solidified at a rate of about 10^2 K/s.

Table 13 Powder production methods

(a) VIM, vacuum induction melting.

(b) VAR, vacuum arc remelting; ESR, electroslag remelting.

(c) RSR, rapid solidification rate.

Fig. 17 Gas atomization system for superalloy powder production. (a) Atomization nozzle. (b) Typical system. Source: Ref 28

The spherical powder is collected at the outlet of the atomization chamber. The maximum particle diameter resulting from this process depends on the surface tension, γ , viscosity, η , and density, ρ , of the melt, as well as the velocity, v , of the atomizing gas. The principal factor is gas velocity. Oxygen contents are of the order of 100 ppm, depending on particle size. Finer particle sizes are obtained by screening. Generally, spherical fine particles are desired for further processing (Ref 2).

Another important powder production method, the soluble gas process, is based on the rapid expansion of gas-saturated molten metal, resulting in a fine spray of molten droplets that form as the dissolved gas, usually hydrogen, is suddenly released (Ref 28) (Fig. 18). The droplets solidify at a rate of about 10^3 K/s, and the cooled powder is collected under vacuum in another chamber, which is sealed and backfilled with an inert gas. This method is capable of atomizing up to 1000 kg (2200 lb) of superalloy in one heat and produces spherical powder that can be made very fine. This method has been successfully employed for LC Astroloy, MERL 76, and IN-100.

Fig. 18 Soluble gas atomization system for producing superalloy powder. Source: Ref 28

The third method of powder preparation is based on centrifugal atomization. The melt is accelerated and disintegrated by rotating under vacuum or in a protective atmosphere. One example of this method is the rotating electrode process (REP) used in the early production of IN-100 and René 95 powder. In this process, a bar of the desired composition, 15 to 75 mm (0.6 to 3 in.) in diameter, serves as a consumable electrode. The face of this positive electrode, which is rotated at high speed, is melted by a direct current electric arc between the consumable electrode and a stationary tungsten negative electrode. The process is carried out in helium. Centrifugal force causes spherical molten droplets to fly off the rotating electrode. These droplets freeze and are collected at the bottom of the tank, which is filled with helium or argon. A major advantage of this process is the elimination of ceramic inclusions and the lack of any increase in the gas content of the powder relative to the alloy electrode.

A variant on the REP process is the plasma rotating electrode process (PREP). Instead of a tungsten electrode, a plasma arc is used to melt the superalloy electrode surface. Cooling rates are higher, up to 10^5 K/s for IN-100 powder. On average, particle sizes are nearly twice as large in these processes as in gas atomization. Neither REP nor PREP processes are currently in active production for superalloys (Ref 28).

When solidification rates of powder exceed 10^5 K/s, the process is referred to as rapid solidification rate (RSR). For superalloys, the objective of the high rates is to obtain a microcrystalline alloy rather than an amorphous material. Apart from extremely fine grain size, such powders display nonequilibrium solubilities and very uniform compositions because of the very fine dendritic arm spacings resulting from rapid solidification. Both conventional superalloys and new alloys based on Ni-Al-MoX alloys, where X = Ta or W, have been prepared by RSR.

Rapid solidification processing can be done by centrifugal atomization with forced convective cooling, as in the method shown in Fig. 19. In this method, the alloy is vacuum induction melted in the upper part of a chamber. The chamber is then back-filled with helium, and the alloy is poured in a preheated tundish. The liquid is poured through the tundish

nozzle onto a rotor that is spun at 24,000 rev/min. The melt is accelerated to rim speed and then ejected longitudinally as droplets. Further atomization and cooling of the droplets is accomplished by the injection of helium gas through annular nozzles. Spherical powder in the 10 to 100 μm (400 to 4000 $\mu\text{in.}$) diam range is produced; the cooling rate typically varies between 10^5 and 10^7 K/s, the higher rates being achieved with the smaller particles.

Fig. 19 Schematic of Pratt and Whitney powder rig for producing rapidly solidified powders. Source: Ref 2

Rapidly solidified powders may also be prepared from melt spun ribbon that is pulverized after solidification. The ribbon is produced by pouring the melt through an orifice under pressure and impinging it on a rotating wheel of, for example, copper, that acts as a heat sink. Typical cooling rates are approximately 10^6 K/s, and ribbon thicknesses are less than 25 μm (1000 $\mu\text{in.}$). The ribbon must be mechanically pulverized, and this method is generally limited to small quantities of experimental alloys.

Powder Consolidation. Although virtually every P/M consolidation technique has been applied to superalloys, production is presently limited to hot isostatic pressing (HIP) and related processes and to hot compaction followed by extrusion (Ref 28), in which extrusion is carried out to achieve full density.

A key feature of any consolidation process is the necessity to minimize contamination, especially from absorbed surface gases and organic material mixed in with the powder. Therefore, powders are packed into sheet metal containers under dynamic vacuum (either warm or cold). The evacuated container is then sealed, heated to the desired temperature, and then compacted, either isostatically under gas pressure or in a closed die.

The advantage of hot isostatic pressing is that a fully dense product can be obtained without retained prior particle boundaries (PPBs). The densification mode is either plastic deformation or creep, depending on the HIP cycle time, temperature, and pressure. Grain size control during hot isostatic pressing is achieved by choosing a temperature either above or below the γ' solvus.

The advantage of extrusion is greater certainty in breaking up reaction areas that are due to organic contamination. Extrusion has been used for a significant portion of consolidation in production. The hot compaction that precedes extrusion is usually carried out below the solvus.

Recently, both glassy and ceramic containers have been used for hot isostatic pressing (Ref 2). Glassy containers are weak and cannot support the weight of a large part. However, a ceramic container inserted into a large steel container allows the production of intricate shapes. During the HIP, the outer metal jacket can be subjected to the autoclave gas pressure. The pressure is transmitted to the ceramic mold through a bed of fine alumina powder.

Other powder consolidation techniques related to hot isostatic pressing are the consolidation by atmospheric pressure (CAP) process and the fluid die process (Ref 2). Neither technique requires an expensive HIP unit. The CAP process resembles a vacuum sintering process, assisted by low pressure exerted on the surface of a shaped glass container. The fluid die process incorporates a cavity surrounded by a dense, incompressible mass of material. The higher mass of these containers, compared to sheet containers, allows greater vibration during filling and selling, ensuring more complete filling and uniform tap density. The outer material softens appreciably at the compaction temperature, allowing pressure to be transmitted to the powder. Convectional die forging equipment is capable of much higher ram pressures than those possible with HIP autoclaves; full consolidation occurs in less than 1 s.

Thermomechanical Working (Ref 2, 24, 25). Processing by thermomechanical means achieves hot deformation that can neutralize the detrimental effects of the contamination of superalloy powder by ceramic inclusions, rubber, cloth, mill scale, and similar debris. In addition, the super-plastic behavior of some P/M superalloys, when grain size is in the range of 1 to 10 μm (40 to 400 $\mu\text{in.}$), leads to improved formability so that near-net shape parts can be more readily produced. Thermomechanical processing also can modify grain shape, size, and orientation; dislocation substructure; and grain-boundary morphology, in addition to producing necklace structures, which may result in improved fatigue crack growth behavior because of their microstructure.

In the Pratt and Whitney Gatorizing process, initially fine-grain P/M preforms are isothermally forged to improve structural uniformity relative to other consolidation methods. A high volume fraction of γ' is required to stabilize the grain size during forging. The fine grain structure is achieved by extrusion of previously compacted preforms or by direct powder extrusion. These alloys exhibit high strain rate sensitivity, making strain rate control during forging critical.

Oxide Dispersion Strengthened Alloys. An important application of P/M techniques is the production of oxide dispersion strengthened superalloys. Commercial alloy compositions are listed in Table 14 and are based on either nickel or iron-chromium-aluminum matrices.

Table 14 Oxide dispersion strengthened superalloys

While a variety of methods has been used to incorporate particles in a ductile matrix, the only commercial technique currently being employed is mechanical alloying. In this proprietary process, a controlled mixture of alloy powder and about 1 vol% oxides (typically Y_2O_3) are charged into a high-energy ball mill. The metal particle size initially is in the 2 to 200 μm (80 to 8000 $\mu in.$) range, while the oxide particles are less than 10 μm (<400 $\mu in.$) in size. The milling operation, carried out dry, causes the superalloy particles to weld repeatedly to the oxide particles and then break apart. The resultant, acicular or platelike powders are composites with extremely fine, homogeneous microstructures. Consolidation is carried out by placing the powders in steel cylinders, aligning the ends closed, and either extruding to bar or rolling to plate or sheet.

Hard particles produced by mechanical alloying are strengthened by impeding dislocation motion. An addition factor affecting the strength of these alloys is the elongated grain structure resulting from extrusion or rolling. The Y_2O_3 particles in the mechanically alloyed materials listed in Table 14 are fine and quite uniformly dispersed. The hardening due to these factors must be added to the strengthening effect of grain boundaries, subboundaries, and solid-solution additions. An additional factor is the grain aspect ratio (GAR), or the ratio of grain length, D , to width, d . At high temperatures, tensile strength varies approximately linearly with GAR (Ref 29).

Creep and stress rupture behaviors also correlate well with GAR, as shown in Fig. 20 for MA 753 at 1040 °C (1900 °F) (Ref 30). Wilcox and Clauer (Ref 29) concluded that when grains are elongated, the GAR effect swamps any contribution of grain size. As shown in Fig. 7(b)), the strength of Ma 6000 is greater than that of most cast or cast and wrought alloys at temperatures above 1000 °C (1830 °F).

Fig. 20 Influence of grain aspect ratio on stress for 100-h life for MA 753 at 1040 °C (1900 °F). Source: Ref 13

A further advantage of mechanical alloying is a much higher ratio of fatigue resistance to tensile strength relative to that of precipitation-hardened alloys.

The thermomechanical processing of ODS alloys is carried out by standard superalloy procedures because grain size is fine and alloys such as MA 6000 can be deformed superplastically (Ref 27). A critical level of warm deformation (815 to 1100 °C, or 1500 to 2010 °F) is required for subsequent recrystallization at higher temperature (<1200 °C, or 2190 °F) to produce coarse, elongated grains with the desired cube-on-edge texture. Finally, heat treatment is carried out to control γ' size and carbide distribution.

The ODS alloys have applications in hot sections of aircraft gas turbines, in powder generation equipment, in furnaces, and in the chemical process industries. For example Inconel MA 6000, which is also strengthened by γ' , is suitable for turbine blades, while the solid-solution alloy Inconel MA 754 is a turbine vane alloy and has applications in which resistance to impure helium (in gas-cooled nuclear reactors) or to corrosive liquids such as molten glass is required. The iron-base sheet alloy MA 956 has been developed for service at temperatures above 1100 °C (2010 °F) in corrosive atmospheres.

Mechanical Properties (Ref 28). Monotonic P/M superalloy properties are directly related to the composition and structure of the alloy. In turn, the structure is related to powder particle size, consolidation process, and heat treatment. For example, the effects of grain size and heat treatment on the tensile properties of René 95 are obvious in Table 15, which shows that tensile strength and ductility increase as grain size becomes finer (Ref 28, 31). However, when René 95 is heat treated above the γ' solvus temperature, both grain size and stress-rupture life increase, while tensile yield decreases, as shown in Table 16.

Table 15 Heat treatments, grain size, and tensile properties of René 95 forms

Heat treatment/property	Extruded and forged ^(a)	Hot isostatic pressing ^(b)	Cast and wrought ^(c)
Heat treatment	1120 °C (2050 °F)/1 h AC + 760 °C (1400 °F)/8 h AC	1120 °C (2050 °F)/1 h AC + 760 °C (1400 °F)/8 h AC	1220 °C (2230 °F)/1 h AC + 1120 °C (2050 °F)/1 h AC + 760 °C (1400 °F)/8 h AC

Controlling the cyclic mechanical properties of superalloys, particularly low-cycle fatigue (LCF), is important to gas turbine engine performance and reliability improvements. Low-cycle fatigue is primarily controlled by defects in the material that result in the initiation of fatigue cracks by any mechanism that is noncrystallographic in nature. The effects of defects on low-cycle fatigue depend on the size and location of the defects in the LCF specimen. (The defects themselves, in terms of size and distribution, are dependent on powder particle size and consolidation process.) A defect of a given size is less detrimental when located internally rather than externally. This is primarily due to the absence, when internal, of adverse environmental interaction (Ref 28).

The effects of thermomechanical working on low-cycle fatigue also are important. As shown in Fig. 21, extruded and forged material showed longer life than the average HIP or HIP and forged materials (Ref 28, 32). The effects of forging are that defects are dispersed during processing, their size may be reduced, and the grain size is further refined. Controlling the thermomechanical process can reduce or even eliminate the effects of PPB defects. The LCF life of a thermomechanically processed P/M superalloy does appear to be limited by small ceramic defects (Ref 28).

Fig. 21 Comparison of average low-cycle fatigue lives of HIP versus extruded and forged and versus HIP and forged René 95. Source: Ref 28, 32

Test conditions and alloy chemistry also are factors in fatigue resistance. This may best be seen in Fig. 22, which compares the strain-controlled fatigue lives of seven superalloys. At low strain amplitude, the strongest alloys (for example, René 95 and MERL 76) are the most fatigue resistant, while at high strain amplitudes, the weakest alloys (Waspaloy and HIP Astroloy) display the longest lives. The crossover in ranking of the various alloys occurs because strength is the most important variable at low strain amplitudes, while ductility dominates at high strain amplitudes.

Fig. 22 Comparison of cyclic strain control LCF properties of seven nickel-base alloys tested at 650 °C (1200 °F). Source: Ref 33

For alloys that are highly oxidation resistant, the stress-rupture properties of bar and sheet of the same alloy differ little. However, less oxidation-resistant alloys are likely to exhibit lower properties for sheet than for bar of the same composition. Similarly, elevated-temperature fatigue properties are very susceptible to changes in environment. Oxygen and sulfur are particularly harmful with respect to crack growth at elevated temperatures. The application of a coating may actually decrease fatigue resistance at high stress or strain levels because of alterations in microstructure induced by the coating treatment. Long-time exposures of coated materials, however, should yield superior fatigue properties.

Selected P/M superalloy mechanical properties are provided in Table 17, while those of ODS materials are given in Table 18. It should be noted that mechanical properties can change significantly with changes in processing conditions and chemical compositions. In particular, changes in grain size and precipitate distribution that result from processing can have a substantial influence on strength.

Appendix: P/M Cobalt-Base Wear-Resistant Materials

R.J. Dawson and E.M. Foley, Deloro Stellite, Inc.

Alloys based on cobalt chromium-tungsten-carbon, such as the Stellite family of alloys, are extremely versatile, wear-resistant materials (Ref 40, 41, 42, 43, 44, 45). They are particularly effective when high temperature or corrosive conditions are combined with abrasive, erosive, or metal-on-metal wear conditions. These materials retain their hardness at elevated temperatures and excel in applications in which lubrication cannot be used.

Full density P/M components can now be manufactured by hot isostatic pressing or extruding operations (Ref 46, 47). Powder metallurgy processing offers the advantages of economical automation, near-net shape processing, and resulting refined microstructures.

Material Descriptions and Applications. Table 19 gives the nominal chemical analysis for the most popular Stellite P/M materials. The microstructure of Stellite alloys contains complex combinations of M_7C_3 , M_6C , and $M_{23}C_6$ carbides embedded in a cobalt-chromium-Tungsten superalloy matrix. Figure 23 shows a range of structures that can be tailored to give a desired combination of wear, corrosion, and mechanical properties.

Table 19 Nominal chemical analysis of most widely used Stellite P/M materials

(a) Maximum; all materials cobalt base

Fig. 23 Microstructure of Stellite P/M materials. Chromium and tungsten alloy carbides are supported by a cobalt-base superalloy matrix. Carbide level varies from 5 to 60 vol%. (a) Stellite 12. (b) Stellite 31. (c) Stellite 98M2. 500×

For highly abrasive conditions, alloys such as Stellite 3, 98M2, and Star J are preferable because they contain a large volume fraction of carbides. The lower carbon grades are more ductile and are suitable for applications involving shock loading or impact.

Figure 24 shows a range of Stellite P/M components. Typical applications include precision balls, bearing race blanks, valve seat inserts, saw tips, cutters, spacer bushings, and wear pads. Figure 25 shows stainless steel needle holders with Stellite 3 serrated-jaw inserts, which are widely used in the medical surgical field. Because Stellite 3 is more ductile than is tungsten carbide, the serrations are less prone to chip off. The corrosion resistance of Stellite 3 makes it more compatible with body fluids and easier to clean. Brazing of the jaw inserts is also much easier with Stellite 3 because the thermal expansion characteristics of Stellite 3 are closer to those of the stainless steel forging.

Fig. 24 Typical Stellite P/M components

Fig. 25 Stellite P/M needle holder inserts manufactured from one of the harder wear-resistant cobalt-chromium-tungsten-carbon alloys

Material Properties. Tables 20 and 21 show the physical and mechanical properties of Stellite materials. The physical properties were measured on castings, but are thought to be representative of P/M parts. It should be noted that Stellite materials are only weakly magnetic under most conditions.

The excellent hot hardness of the materials is particularly important to prevent the dulling of cutting tools where frictional heating is typically extreme at the sharp edge. It may be noted that some grades, such as Stellite 31, are relatively soft and ductile. This grade is used when high-temperature strength, shock loading, fatigue, and fretting are concerns.

Service Performance Tests. Stellite 12 P/M has proved to be exceptional for cutting timber. Table 22 compares the dulling of tungsten carbide and Stellite 12 P/M for four types of wood. The dulling of the teeth was measured at various stages of wood cutting. Corrosion by wood acids at high temperature is the main cause of dulling. The primary reason that Stellite alloys outperform tungsten carbide is that the wear of Stellite 12 P/M teeth is insensitive to the wood species being cut.

Table 22 Tool wear rate of saw teeth when cutting various green woods

Wood	Stellite 12 P/M		W-6% Co	
	µm/km	µin./mile	µm/km	µin./mile

Western red cedar	0.29	19	0.87	56
White spruce	0.28	18	0.50	32
Southern pine	0.31	20	0.40	26

Bearing performance was simulated in a Rolltact test, as shown in Fig. 26. Test results shown in Table 23. It is worth noting that the P/M balls outperformed their cast counterparts. This was attributed to the fine P/M structure. The wear of the cups and separators was also reduced. The crush strength of the P/M balls was measured and found to be nearly twice that of the cast balls.

Table 23 Rolltact test component wear

Material Parameter		Component wear ^(a)

(a) In terms of average weight loss from three tests. Gr, grain

Fig. 26 Schematic of Rolltact test, in which component wear indicates expected wear of a rolling contact bearing operated under similar conditions. The drive ball and cup, alternate balls, and test separator are representative of a full-scale bearing. Test conditions are: spindle speed, 2000 rev/min; contact angle, 30°; contact load, 1380 MPa (200 ksi); test duration, 20 h; environment, deionized water at 22 °C (72 °F) in air

Heat Treatment. Stellite P/M materials are not generally considered heat treatable, nor is heat treatment required. Stress relief treatment involves a slow heat-up and soaking at 900 °C (1650 °F) for at least 2 h, followed by furnace cooling. Stellite 6 can be solution annealed by soaking at 1200 °C (2190 °F) for 2 h followed by rapid cooling. This maximizes the corrosion resistance and ductility of Stellite 6. Stellite 31 can be age hardened using a 2-day aging treatment at 800 °C (1470 °F).

Joining. Stellite materials can be joined to other materials by brazing or welding. Flame brazing is typically done with silver solder and an oxyacetylene flame. Vacuum furnace brazing uses a nickel-base brazing alloy such as AMS 4777.

Gas tungsten arc and gas metal arc resistance welding are commonly used for Stellite P/M materials. For the fusion processes, a preheat of 810 °C (1490 °F) is required for the harder grades, such as Stellite 3, 19, 98M2, and Star J. The softer grades, such as Stellite 6 and 31, should be preheated to 540 °C (1005 °F). Furnace cooling is required for the harder grades, whereas cooling in still air is satisfactory for the softer grades. Stellite 25 or Nistelle W filler metals are recommended for joining Stellite material to mild steel or stainless steel.

Machining. With the proper machine setup, Stellite alloys can be rough machined. Alloys having hardnesses of less than 55 HRC can usually be machined, whereas alloys having hardnesses greater than 60 HRC are normally ground. For better surface finishes, any of the Stellite wear-resistant alloys should be ground.

These alloys are usually machined with tungsten carbide tools. Tools for turning should have a 5° end relief, 10° side relief, and a side cutting edge angle of 45°. Tools for facing and boring are essentially the same, except for greater clearance where needed. For best results in drilling, the drill web should be kept as thin as possible, using carbide-tipped drills. In reaming, a 45° side cutting edge angle should be used. The tapping of holes is not recommended for any of the harder alloys, but threads can be produced by electrical discharge machining techniques.

Table 24 is a guide to machining these alloys; it has been written to cover the machining of all the alloys and does not necessarily represent the optimum conditions for each. In general, the harder alloys should be machined, starting at the lower end of the speed and feed ranges shown in Table 24. Softer alloys or more rigid setups will allow higher speeds and feeds.

Table 24 Guide for machining Stellite alloys

Operation	Speed		Roughing				Finishing			
			Feed		Depth of cut		Feed		Depth of cut	
	mm/min	ft/min	mm/rev	mils/rev	mm	mils	mm/rev	mils/rev	mm	mils
Turning ^(a)	9-15	30-50	0.203-0.305	8-12	0.127-5.08	5-205	0.152-0.254	6-10	≤0.635	≤25
Facing ^(a)	9-15	30-50	0.203-0.305	8-12	0.127-2.54	5-100	0.152-0.254	6-10	≤0.635	≤25
Boring ^(a)	6-15	20-50	0.127-0.203 ^(b)	5-8	0.635-2.54 ^(b)	25-100	0.127-0.203	5-8	≤0.635	≤25
Drilling ^(c)	3-8	10-26	0.025-0.127 ^(d)	1-5
Reaming ^(e)	3-9	10-30	0.025-0.127 ^(f)	1-5	0.762-1.52	30-60	0.025-0.076 ^(f)	1-3	0.254-0.635	10-25
Threading	Use single-point C-3 tungsten carbide tools at 3-8 m/min (10-26 ft/min)									

(a) C-3 tungsten carbide tools should be used. Coolant is water-base fluid diluted 15 parts water to one part fluid. Tools for facing and boring are basically the same as turning tools, except for greater clearances where needed.

(b) Depends on bar and size of tool.

(c) C-2 tungsten carbide twist drills should be used, with drill web kept as thin as possible. Coolant is same as in (a).

(d) Depends on size of drills.

(e) C-3 tungsten carbide tools should be used. Reamers should have a 45° side cutting edge angle. Coolant is same as in (a).

(f) Per tooth

Grinding. Whenever close tolerances are required, grinding is recommended for finishing Stellite wear-resistant alloys. Recommended wheels and coolants are listed in Table 25. Grinding speeds should be kept between 14 and 31 m/s (45 and 100 ft/s). Alloys being ground dry should not be quenched because this may cause surface checking. Care should be taken in grinding Stellite 98M2, Star J, and Stellite 3 P/M because they are more sensitive to thermal shock than are the other alloys, and flood cooling is recommended.

Table 25 General recommendations for grinding wheels

Purpose	Recommended wheels	Coolant
Peripheral wheels		
Stellite alloy deposits	A60JV	Emulsifying oil
Form grinding (Finer grits recommended for sharper forms)	A100GV A120KV A150GV	Emulsifying oil
Ring wheels		
Mixed Stellite alloy and steel	A46DZB	3.8 L (1 gal) good grade of water-soluble oil plus 190 L (50 gal) water
Stellite alloy only	A50BB	
Segmental wheels		
Mixed Stellite alloy and steel	A46DZB	0.45 kg (1 lb) Sal Soda to 190 L (50 gal) water
Stellite alloy only	A50BB	
Tool and cutter grinding		
Cup wheels	A46JV	3.8 L (1 gal) good grade of water-soluble oil plus 190 L (50 gal) water
Peripheral wheels (see above)		
Internal grinding		
Bores >~100 mm (4 in.) diameter	A54JV,	3.8 L (1 gal) good grade of water-soluble oil plus 190 L (50

	A54MV	gal) water
Centerless grinding <~115 mm (4.6 in.) diameter	A60L-V	3.8 L (1 gal) good grade of water-soluble oil plus 190 L (50 gal) water
Off-hand grinding	A46MV	Dry
Cutting off Stellite alloy	A46QB	1 part water-soluble oil to 60 parts water
Surface grinding		
General Stellite alloy grinding		
For wheels ≤ 305 mm (12 in.)	A60JV	1 part water-soluble oil to 60 parts water
For wheels >305 mm (12 in.)	A46JV	

- (a) Note: Wheels carrying the same marking from different manufacturers do not necessarily have the same cutting action. Wheel descriptions based on ANSI B74.13-1970 and BS 4481

Introduction

SUPERALLOYS are a group of nickel-iron-nickel-, and cobalt-base materials that exhibit outstanding strength and surface stability at temperatures up to 85% of their melting points ($0.85 T_M$). They are generally used at temperatures above 540 °C (1000 °F). Superalloys were initially developed for use in aircraft piston engine turbosuperchargers, and their development over the last 50 years has been paced by the demands of advancing gas turbine engine technology.

The initial cast superalloy developments in the United States centered on cobalt-base materials. Cast Vitallium (Co-27Cr-5.5Mo-2.5Ni-0.25C) turbosupercharger blades were produced by the Austenal Company in 1942 in response to an overloaded forging industry and forgeability problems experienced with the early nickel-chromium-iron solid-solution wrought superalloys. This work ultimately led to the successful manufacture of investment cast components for the first U.S. production gas turbine engine in 1945 (Ref 1).

Nickel-base and nickel-iron-base superalloys owe their high-temperature strength potential to their gamma prime (γ') ($\text{Ni}_3\text{Al,Ti}$) content. The first reference to aluminum or titanium additions to the 80-20 Ni-Cr system occurred in a patent filed by Heraeus Vacuumschmelze A.G. in 1926, in which as much as 6% Al was added to a nickel-chromium-iron alloy for increased tensile yield strength. Not until later in the decade, however, did a French patent application recognize the occurrence of precipitation hardening in nickel-chromium alloys. In 1929, Pilling and Merica concurrently filed a number of patent applications in the United States for precipitation-hardening nickel-base alloys containing aluminum and titanium, and in 1931 the first British patent applications covering aluminum plus titanium additions to nickel-base alloys were filed.

Although age hardening was recognized, it was not until the development of the Whittle engine in Great Britain, along with gas turbine engine developments in Germany, that material creep strength was a recognized consideration. The requirement for creep resistance led to an understanding of the relationship between age hardening and creep, eventually pacing the rate of development of γ' -strengthened nickel-base alloys.

The first commercial nickel-base alloy developmental work, undertaken by the British in the early 1940s, led to the wrought Nimonic 75 and 80 alloys. Increased operating-temperature requirements for U.S. aircraft engines resulted in the use of aluminum plus titanium strengthened wrought materials during the same period of time. Component forgeability problems, however, led to the use of cast Vitallium until the shortages of cobalt supply experienced during the Korean War caused further research on nickel-base alloys.

Cast nickel-base alloy developments outpaced cobalt-base developmental work by the late 1950s because of their superior strengthening potential, that is, stable, coherent intermetallic compound γ' phase introduction. The introduction of commercial vacuum induction melting (VIM) and vacuum investment casting in the early 1950s provided further potential for γ' exploitation. Many nickel-base alloy developments resulted, continuing through the 1960s (Fig. 1). The compositions of cast nickel- and cobalt-base superalloys are listed in Tables 1 and 2, respectively; Tables 3, 4, 5, and 6 list physical and mechanical properties of cast nickel- and cobalt-base superalloys.

Table 1 Nominal compositions and densities of selected cast nickel-base superalloys

Fig. 1 Progress in the high-temperature capabilities of superalloys since the 1940s. Source: Ref 2

The development of new polycrystalline alloys continued through the 1970s, however, at a more moderate rate. Attention was concentrated instead on process development, with specific interest directed toward grain orientation and directional-solidification (DS) turbine blade and vane casting technology (Fig. 2).

Fig. 2 Advances in turbine blade materials and processes since 1960. Source: Ref 4

Applied to turbine blades and vanes, the DS casting process results in the alignment of all component grain boundaries such that they are parallel to the blade/vane stacking fault axis, essentially eliminating transverse grain boundaries (Fig. 3). Because turbine blades/vanes encounter major operating stress in the direction which is near normal to the stacking fault axis, transverse grain boundaries provide relatively easy fracture paths. The elimination of these paths provides increased strain elasticity by virtue of the lower $\langle 001 \rangle$ elastic modulus, thereby creating opportunities for further exploitation of the nickel-base alloy potential.

Fig. 3 The evolution of the processing of nickel-base superalloy turbine blades. (a) From left, equiaxed, directionally solidified, and single-crystal blades. (b) An exposed view of the internal cooling passages of an aircraft turbine blade. Source: Ref 5

The logical progression to grain-boundary reduction is the total elimination thereof. Thus, single-crystal turbine blade/vane casting technology soon developed, providing further opportunity for nickel-base alloy design innovation.

The late 1970s and the 1980s have, therefore, been a productive development period for nickel-base alloys designed specifically for directionally solidified columnar-grain and single-crystal cast components. These new process technologies, which are more fully discussed in the article "Directionally Solidified and Single-Crystal Superalloys" in this Volume, have contributed to dramatic improvements in gas turbine engine operating efficiency.

Polycrystalline Cast Superalloys

Gary L. Erickson, Cannon-Muskegon Corporation

Superalloy Design

Nickel-base superalloys have microstructures consisting of an austenitic face-centered cubic (fcc) matrix (γ) dispersed intermetallic fcc γ' $\text{Ni}_3(\text{Al,Ti})$ precipitates coherent with the matrix (0 to 0.5% lattice mismatch), and carbides, borides, and other phases distributed throughout the matrix and along the grain boundaries. These complex alloys generally contain more than ten different alloying constituents. Various combinations of carbon, boron, zirconium, hafnium, cobalt, chromium, aluminum, titanium, vanadium, molybdenum, tungsten, niobium, tantalum, and rhenium result in the commercial alloys used in today's gas turbine engines.

Some alloying elements have single-function importance, whereas others provide multiple functions. For example, chromium is primarily added to nickel-base alloys for sulfidation resistance (Cr_2O_3 protective-scale formation), whereas aluminum not only is a strong γ' former but also helps provide oxidation resistance when present in sufficient quantity by forming a protective Al_2O_3 scale.

Many of the other alloying elements also have multiple roles. Titanium, while primarily partitioning to the γ' , also participates in the formation of primary (MC) carbides, the hexagonal close-packed (hcp) eta (η) phase, and undesirable nitride and carbosulfide formation. Molybdenum, tungsten, tantalum, rhenium, cobalt, and chromium additions promote solid-solution strengthening, but it is known that tantalum, tungsten, and rhenium may also partition to the γ' to varying degrees and that tantalum and rhenium may also be beneficial to environmental resistance properties.

Vanadium is a γ' partitioner, but it also promotes the formation of M_3B_2 -type borides. Niobium forms the intermetallic phases delta (δ) (orthorhombic Ni_3Nb) and γ'' (body-centered tetragonal Ni_3Nb), but it is also involved in the formation of Laves ($\text{Fe,Ni}_2\text{Nb}$) phase, carbides, borides, and/or nitrides. Hafnium is a strong carbide former that is added to polycrystalline alloys to improve grain-boundary ductility. However, at the same time, it increases the volume fraction of γ/γ' eutectic and increases oxidation resistance. Carbon, boron, and zirconium are used at varying levels for grain-boundary strengthening.

All of these constituents interact in various ways to provide high tensile, creep, and fatigue strengths, plus oxidation and sulfidation resistance. Proper control of the cast microstructure and subsequent solutioning and aging treatments generally result in satisfactory component performance.

Under the extreme temperature/stress conditions in which superalloy components operate, however, microstructural features change, often with attendant property changes. The microstructural instabilities that may occur include:

- Intermetallic phase precipitation (σ , μ , Laves)
- Phase decomposition (carbides, borides, nitrides)
- Phase coalescence and coarsening (γ')
- Phase solutioning and reprecipitation (γ')
- Order-disorder transition
- Material oxidation
- Stress-corrosion cracking

The formation of topologically close-packed phases (σ , μ , and so on) generally decreases rupture properties. Their occurrence is controlled through chemistry adjustment and is fairly predictable through use of the commonly accepted methods of calculating the so-called electron vacancy number, N_v , of the given alloys. Different calculation methods exist; however, all provide a useful key to the prediction of σ formation when proper reference points are known.

Although it occurs during both solidification and heat treatment, carbide precipitation is generally promoted during component heat treatment to effect an optimum grain-boundary carbide morphology and population. Discrete, blocky $M_{23}C_6$ particles distributed in a discontinuous fashion are preferred. High-temperature, stressed exposure tends to cause carbide degeneration, often resulting in grain-boundary overload and compromised rupture strength.

MC-type carbides generally occur during alloy solidification. They are titanium-rich (MC-1) or tantalum-rich (MC-2) and may partially degenerate with high-temperature exposure to form hafnium-rich (MC-3) carbides and/or $M_{23}C_6$, M_7C_3 , and M_6C carbides (secondary carbides); the specific type depends upon alloy chemistry and exposure temperature. The chromium-rich $M_{23}C_6$ generally forms at the grain boundaries in polycrystalline materials; when present as discrete, discontinuous particles, it provides the grain-boundary strength and resistance to fracture needed to prolong service life.

On the other hand, carbide degeneration also releases titanium and tantalum to the solid-solution matrix, resulting in further matrix saturation. Oversaturation can result in the formation of undesirable secondary phases such as μ (tungsten- and/or molybdenum-rich), α -W, α -Cr, and/or M_6C carbides, making chemistry balancing and controlled thermal treatment necessary for ultimate success.

Superalloys are, indeed, complex. However, careful alloy design and processing will provide the desired results. Simply stated, superalloy property attainment is principally a function of the amount and morphology of the γ' , grain size and shape, and carbide distribution. Early superalloys contained less than 25 vol% γ' . However, commercial vacuum induction refining and casting provided the opportunity for greater γ' volume fraction, to the extent that today's commercial superalloys generally contain approximately 60 vol% γ' .

This increased level of γ' results in greater alloy creep strength (Fig. 4), but it can be fully exploited only in single-crystal components, where full γ' solutioning is generally possible. For polycrystalline superalloy components, high-temperature strength is affected by the condition of the grain boundaries and, in particular, the grain-boundary carbide morphology and distribution. Optimized properties can be achieved if solutioning and aging treatments are developed to attain discrete, globular carbide formation along the grain boundaries in conjunction with the optimized γ' volume fraction/morphology and component grain structure. Representative stress-rupture curves for selected nickel-base superalloys are shown in Fig. 5. Table 5 also provides stress-rupture data.

Cobalt-base alloys (see Table 2) are designed around a cobalt-chromium matrix with chromium contents ranging from 18 to 35 wt%. The high chromium content contributes to oxidation and sulfidation resistance, but also participates in carbide formation (Cr_7C_3 and M_{23}C_6) and solid-solution strengthening. Carbon content generally ranges from 0.25 to 1.0%, with nitrogen occasionally substituting for carbon.

Cobalt-base alloys are often designed with significant levels of both nickel and tungsten. The addition of nickel helps to stabilize the desired fcc matrix, while tungsten provides solid-solution strengthening and promotes carbide formation. Molybdenum also contributes to solid-solution strengthening but is less effective and potentially more deleterious than a tungsten addition. Other alloying elements contributing to the solid solution and/or carbide formation are tantalum, niobium, zirconium, vanadium, and titanium.

These additions provide strength by means of solid-solution and second-phase strengthening. No intermetallic precipitated phase has been discovered to equal the benefit imparted by γ' nickel-base superalloys. Solid-solution strengthening results principally from the chromium, tantalum, niobium, and tungsten additions, while second-phase strengthening is obtained primarily from the carbides and carbonitrides formed with chromium. The multiple-composition complex carbides may be present as MC, M_6C , M_7C_3 , M_{23}C_6 , and M_2C_3 .

As with nickel-base superalloys, carbides must be precipitated at grain boundaries to control gross grain-boundary sliding and migration. Optimum mechanical properties are obtained through the careful balancing of the carbides at grain boundaries and within the matrix. When carbides are present in sufficient quantity, the skeletal carbide network that results can contribute to component strength much like the strengthening that is achieved in a composite (Ref 9).

Most cobalt-base alloy aerospace castings are not heat treated apart from a relatively low-temperature stress-relief anneal. Carbide distribution is, therefore, determined during solidification, thereby highlighting the need for stringent control of the alloy pouring temperature and cooling rate during and after solidification. Exceptions to this may be found in medical applications, where cobalt-base alloy castings for orthopedic implants are sometimes solution treated. Representative stress-rupture curves for selected cobalt-base alloys are shown in Fig. 5(c) and 5(e). Table 6 also provides stress-rupture data.

Polycrystalline Cast Superalloys

Gary L. Erickson, Cannon-Muskegon Corporation

Vacuum Induction Melting of Superalloys

Commercial vacuum induction melting was developed in the early 1950s, having been stimulated by the need to produce superalloys containing reactive elements within an evacuated atmosphere. The process is relatively flexible, featuring the independent control of time, temperature, pressure, and mass transport through melt stirring. As such, VIM offers more control over alloy composition and homogeneity than all other vacuum melting processes.

The primary purification reaction occurring in the process is the removal of melt-contained oxygen by means of a reaction with carbon to form carbon monoxide (CO). The reaction occurs most readily at or near the melt surface with the reaction kinetics being affected by crucible geometry and melt stirring. The removal of oxygen from the melt as CO is favored by decreased melt chamber pressure, elevated bath temperature, and increased carbon activity (Ref 10).

The melting crucible material is not inert and is actually another source of oxygen and other impurities, depending on refractory type and condition. Therefore, both melt refining temperature and refining duration are carefully scrutinized. Proper melt stirring is integral to the deoxidation process and must be optimized through proper furnace power frequency and application procedure to prevent refractory lining erosion, a potential problem particularly during the controlled but more vigorous CO boiling portion of the process.

Vacuum induction melting deoxidation, that is, the generation of CO gas, proceeds as CO bubbles are nucleated heterogeneously along the walls and, sometimes, bottom of the melt/lining-refractory interface. This occurs preferentially at small crevices existing in the lining, with the bubbles growing during movement toward the molten metal/vacuum interface (Ref 11, 12, 13). Actual bubble formation is dependent on the number of gas molecules present; the pressure in the liquid at the level of the bubble; the temperature of the gas; and, for very small bubbles, the interfacial tension between the gas and the liquid metal. Figure 6 shows bubble formation during the VIM process.

Fig. 6 Vacuum induction refining process

Following formation, bubble growth and mass transport within the liquid toward the liquid/vacuum interface is dependent on:

- The quantity of the dissolved gas
- The decreased pressure exerted on the bubble as it rises in the melt
- The bath temperature
- The time it takes for the bubble to rise through the melt to the surface, which, in turn, is a function of melt stirring
- The pressure above the melt
- The interfacial tension between the bubble and the liquid metal

The relatively vigorous, but controlled, portion of the boiling process results in the greatest CO removal. Concurrently, a slight nitrogen loss is realized because of scavenging associated with the CO bubbles, and a slight sulfur reduction may occur during the CO supersaturation stage via sulfur dioxide (SO_2) evolution. Minor tramp elements such as lead, silver, bismuth, selenium, and tellurium, which are deleterious to alloy elevated-temperature rupture strength and ductility (Ref 14, 15), are partially evaporated during this period as well as throughout the entire refining process (Ref 16, 17). Some undesirable elements, however, such as arsenic and tin, must be controlled through raw material selection because they are not removed by vacuum refining. Figure 7 shows the effects of VIM time and temperature on tramp element concentration. Once the boiling subsides, surface desorption of additional CO occurs, and it is during this nonboiling period that nitrogen removal (desorption) is most effective (Ref 18).

Fig. 7 Evaporation of elements from an 80Ni-20Cr alloy during VIM

Refractory Materials. Superalloy melting is generally undertaken in a relatively unreactive, high-bond strength, high-purity MgO-Al₂O₃ spinel refractory lining. Refractories may be monolithic or brick and mortar, with the former providing the greater potential for alloy quality. By minimizing extremes in thermal cycling; optimizing alloy sequencing; and refining temperature, time, and pressure, alloys practically void of any lining-related nonmetallics can be produced.

The types of raw materials and the melt procedure vary depending on the quality of alloy being produced. Alloys destined for critical application, the components of which may be difficult to cast, are produced using the highest-quality raw materials commercially available, in conjunction with sophisticated melt processing. Lower-quality raw materials, such as GMR-235 or IN-713 C, are used for commercial application, such as nonrotating, noncritical, or nonaerospace use, for example, turbocharger wheels, because a higher-quality alloy product is not necessary. The more sophisticated alloy systems are generally produced to premium-quality or integral wheel quality levels, with special attention given not only to cleanliness but also to specific microstructural characteristics and/or chemistry requirements to assist castability, weldability, and component mechanical properties.

The Melt Process. Base charge materials are layered in the relatively warm furnace, in a manner which recognizes and accommodates the elemental melting point of the material and bridging tendency. Only those materials with oxides that are relatively easily reduced for the encountered melt conditions are placed in the initial furnace charge along with a small, controlled carbon addition. Also, those elements that have a particularly strong affinity for nitrogen may be withheld from the base charge because they lower the activity of the dissolved nitrogen.

Following furnace evacuation and particular heat-up cycles that ensure proper closure of any refractory lining cracks prior to metal liquation, optimum temperature and vacuum pressure, consistent with promoting a somewhat vigorous CO boil, is attained. Bath refining is undertaken at a temperature and duration long enough to reach the so-called system equilibrium conditions, the assurance of which is provided by the attainment of consistent furnace leak-up rates. At this point, those elements that were held from the base charge because of their relative reactivity toward oxygen, for example, aluminum, titanium, zirconium, and hafnium, are added with an associated solutioning and homogenization procedure.

Dip sample alloy chemistry is checked in a relatively short time period with any necessary chemistry adjustment undertaken. A similar analytical check is undertaken prior to pouring.

Pouring proceeds once the correct chemistry is ensured, the bath is properly solutioned/homogenized, and the proper pour temperature is attained. It is generally undertaken under high vacuum condition and proceeds from the furnace crucible into a relatively sophisticated multicompartiment tundish, thereby ensuring that extensive time for flotation is achieved

and also that laminar flow conditions prevail in the final separation and pour compartments. The flow-rate controlling, high-alumina tundish system results in a relatively slow pouring rate, effectively maximizing alloy cleanliness.

Filters. One of the most critical stages with respect to cleanliness is the pouring of the melt. Ceramic foam filters are used in some master metal operations to remove relatively large melt inclusions by means of entrapment. Foam filters are most effective where extremely high pour rate conditions and gross cleanliness problems prevail. Filter performance often varies because of the occasional use of filters with poor mechanical strength and/or thermal shock resistance. Foam cell particle breakage often results from handling during shipment or tundish installation and, if undetected, results in filter particulate in the alloy bar stock and subsequently cast components. Optimized VIM technology and practice without filters provide a clean alloy, without the inherent risks associated with filter use when applied to master metal production.

Alternative Melt Techniques. Electron beam, cold hearth refining systems have been shown to be effective for nonmetallic-inclusion removal from superalloys. Initial problems occurring during the process that are associated with analytical control, for example, chromium evaporation, have almost been resolved. However, the process is not currently cost effective for virgin cast superalloy production, although use may be found for powder metallurgy (P/M) superalloy production and/or revert scrap reclamation in the future. Vacuum arc skull melting and casting technology may also be used for superalloy castings.

A plasma melting/refining facility for the production of superalloy powder metal is currently being commissioned. Plasma melt investment casting trials have been undertaken, but no data are currently available. Skull casting development would also help pace the interest in this secondary refining technology. Each of the above-mentioned techniques is described in detail in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Polycrystalline Cast Superalloys

Gary L. Erickson, Cannon-Muskegon Corporation

Quality Considerations

Cast cobalt-base superalloys have large application in the aerospace, medical, and chemical industries. Nickel-base superalloys are used in a wide range of applications also, although most are related to the aerospace industry. For aerospace applications, the quality level required for static components differs tremendously from that required for critical, highly stressed rotating components. Thus, it is useful to classify superalloy products according to quality level.

Superalloy quality can be categorized as commercial grade, aerospace quality, or premium grade. Commercial-grade alloys may be produced with select materials, foundry revert, and/or lower-quality elemental raw materials. Aerospace quality materials may also be produced with select, revert, and/or virgin materials. However, the resulting quality, as measured by cleanliness and gas and tramp element content, is greater. Premium grades are produced for blade/vane airfoil, wheel, and structural-part applications using top-quality raw materials and sophisticated VIM procedures. Typical gas and tramp element level data for the three grades are presented in Table 7.

Table 7 Quality level (allowable tramp element concentrations) for selected nickel-base superalloys

Element	IN-718/MAR-M 247, typical alloy concentration					
	Commercial grade		Aerospace quality		Premium quality	
	Tooling applications	Other

(a) (a) + = or higher

Stringent control of alloy gas and tramp element content is paramount to achieving satisfactory foundry performance and component mechanical property response. Low gas content is desired because oxygen in the alloy is present as nonmetallic stable oxide inclusions, which affect weldability and mechanical properties. Nitrogen also is controlled because it induces microporosity in castings and, when sufficiently high, causes agglomerated microporosity. Nitrogen promotes alloy/crucible wetting during precision investment casting operations and may also be involved in deleterious titanium carbonitride particle formation.

Superalloy silicon content is controlled to low levels because it adversely affects mechanical properties and may cause hot-short cracking during welding operations. In the case of IN-718, silicon is avoided because it also impedes the rate of Laves phase transformation. Low sulfur content is also desired because it tends to migrate to grain boundaries, thereby decreasing hot ductility and promoting cracking. In addition, it can be deleterious to fatigue strength and contribute to increased alloy/crucible wetting during precision casting.

Zirconium is added to superalloys to control grain-boundary strength. However, it is minimized in alloys that undergo extensive welding because it increases the tendency for cracking in the weld and heat-affected zone of the base material.

Polycrystalline Cast Superalloys

Gary L. Erickson, Cannon-Muskegon Corporation

Investment Casting of Superalloys (Ref 19)

A number of casting processes can provide near-net shape superalloy cast parts, but essentially all components are produced by investment casting (Fig. 8). The characteristic physical and mechanical properties and complex, hollow shape-making capabilities of investment casting have made it ideal for amplifying the unusual high-temperature properties of superalloys.

Fig. 8 Basic steps in the investment casting process. See Fig. 9(a) for a close-up of an automated slurry coating process. Source: Ref 4

Cast superalloys are made in a wider range of compositions than are wrought alloys. Creep and rupture properties of a given superalloy composition are maximized by the casting and heat-treatment processes. Ductility and fatigue properties of polycrystalline materials are generally lower in castings than in their wrought counterparts of similar composition. The gap, however, is being reduced by new technological developments to eliminate casting defects and refine grain size.

Investment Casting Process

Patterns, Cores, and Molds. The first step in the investment casting process is to produce an exact replica or pattern of the part in wax, plastic, or a combination thereof. Pattern dimensions must compensate for wax, mold, and metal shrinkage during processing. If the product contains internal passages, a preformed ceramic core is inserted in the die cavity, around which the pattern material is injected. Except for large or complex castings, a number of patterns may be assembled in a cluster and held in position in order to channel the molten metal into the various mold cavities. Design and positioning of the runners and gating is critical to achieving sound, metallurgically acceptable castings. Today the molds are produced by first immersing the pattern assembly in an aqueous ceramic slurry (Fig. 9). A dry, granular ceramic stucco is applied immediately after dipping to strengthen the shell. These steps are repeated several times to develop a rigid shell. After slow, thorough drying, the wax is melted out of the shell, and the mold is fired to increase substantially its strength for handling and storage. An insulating blanket is tailored to the mold configuration to minimize heat loss during the casting operation and to control solidification. More information on the production of patterns, cores, and shells for investment casting is available in the article "Investment Casting" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Fig. 9 (a) Automated slurry coating of an investment casting mold. (b) Cutaway view of a shell mold for an air-cooled turbine blade casting. Source: Ref 5

To make equiaxed-grain castings, the mold is preheated to enhance mold filling, control solidification, and develop the proper microstructure. For vacuum casting, the alloy charge is melted in an isolated chamber before the preheated mold is inserted, and the pressure is maintained at about 1 μm for pouring. After casting, exothermic material is applied as a hot top for feeding purposes, and the mold is allowed to cool. A different procedure is followed in the production of directionally solidified (DS) and single-crystal (SC) superalloy castings; this is described in the article "Directionally Solidified and Single-Crystal Superalloys" in this Volume and in the article "Directional and Monocrystal Solidification" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

The Casting Process. Most superalloys are cast in vacuum to avoid the oxidation of reactive elements in their compositions. Some cobalt-base superalloys are cast in air using induction or indirect arc rollover furnaces. The vacuum casting of equiaxed-grain products is usually done in a furnace divided into two major chambers, each held under vacuum and separated by a large door or valve. The upper chamber contains an induction-heated reusable ceramic crucible in which the alloy is melted. Zirconia crucibles are commonly employed; single-use silica liners may be specified when alloy cleanliness is especially critical.

The preweighed charge is introduced through a lock device and is melted rapidly to a predetermined temperature, usually 85 to 165 $^{\circ}\text{C}$ (150 to 300 $^{\circ}\text{F}$) above the liquidus temperature. Precise optical measurement of this temperature is crucial. Metal temperature during casting is much more critical than mold temperature in controlling grain size and orientation; it also strongly affects the presence and location of microshrinkage. When the superheat condition is satisfied, the preheated mold is rapidly transferred from the preheat furnace to the lower chamber, which is then evacuated. The mold is raised to the casting position, and the molten superalloy is quickly poured into the cavity; speed and reproducibility are essential in order to achieve good fill without cold shuts and other related imperfections. Precise mold positioning and pour rates also are imperative. For maximum consistency, melting and casting are automated with programmed closed-loop furnace control. The filled mold is lowered and removed from the furnace.

Shrinkage during solidification is minimized in part by maintaining a head of molten metal to feed the casting; this is achieved by adding an exothermic material immediately after mold removal from the furnace.

Because of thermal expansion differences, the shell mold usually fractures upon cooling, facilitating its removal by mechanical or hydraulic means. Before grit- and sand-blasting operations, the individual castings are separated from the cluster by abrasive cutoff. After shell removal, the cluster is checked by one of several commercially available emission or x-ray fluorescence instruments to verify the alloy identification.

A major portion of the casting cost is in the finishing operations, which remain labor intensive. Superficial surface defects are blended out abrasively within specified limits, and the castings may require mechanical straightening operations before and after heat treatment to satisfy dimensional requirements.

Polycrystalline Cast Superalloys

Gary L. Erickson, Cannon-Muskegon Corporation

Control of Casting Microstructure (Ref 20)

The solidification of investment cast superalloy components is precisely controlled so that the microstructure, which ultimately determines mechanical properties, remains consistent. For example, once the process for a particular component has been defined, the production of these components does not deviate from the agreed-upon steps for the entire production run, which may last many years without proper approval. If steps are changed, it must be shown that the new steps do not cause a degradation in the properties of the component.

To control the solidification of equiaxed-grain castings, the investment caster has several tools at his disposal: facecoats that encourage grain nucleation, pour temperature of the metal, preheat temperature of the shell, shell thickness, part orientation, part spacing, gating locations, insulation to wrap the shells, pouring speed, and shell agitation. However, the investment caster must first fill the shell cavity, prevent hot tears or other cracks, and minimize porosity. If the first two objectives can be met, the investment caster has some freedom to produce the desired structure. If the desired structure still cannot be made, other more complex techniques may be employed, including changing the thermal conductivity of the shell.

Dendrites are probably the most visible microstructural feature in superalloy castings. Primary and secondary dendrite arm spacings are controlled by the cooling rate. As the dendrite arm spacing is reduced, segregation in the dendrite core and interdendritic regions is also reduced, thereby benefitting mechanical properties.

Carbides. Conventional equiaxed-grain nickel-base superalloys typically have 0.05 to 0.20 wt% C, while cobalt-base alloys contain up to about 1.0% C. Both alloy systems may use carbon to increase grain-boundary strength. Cobalt-base alloys require more because internal carbides are one of the primary strengthening mechanisms.

Carbide morphology is controlled by solidification or composition. For example, by increasing the cooling rate, more discrete, blocky-type MC carbides are formed in IN-713 C, and this often results in an improvement of at least two times to low-cycle fatigue (LCF) properties (Ref 21, 22). If it is not possible to influence the cooling rate of a casting significantly, adding small amounts of magnesium, calcium, cerium, or other rare earth metals acting as nucleating agents will assist in carbide shape control.

Eutectic Segregation. By the very nature of solidification, segregation is introduced into the component. Important segregants of interest in cast superalloys are eutectics, which often are found in interdendritic or intergranular regions. In nickel-base alloys, eutectic pools are the last constituents to solidify and have a cellular appearance. The composition of the eutectic pools varies, but they typically contain excess γ' , carbides, borides, and low melting point phases. Control of the eutectic pool is done primarily through composition. However, it has been shown that while the volume fraction of

eutectic remained constant near 0.10 vol% in IN-713, the size of the eutectic pool increased from 11 to 19 μm as the cooling rate decreased from 0.56 to 0.036 $^{\circ}\text{C/s}$ (1 to 0.065 $^{\circ}\text{F/s}$) (Ref 20).

In cobalt-base alloys, the eutectics typically form lamellar γ and M_{23}C_6 pools or colonies. Heat treatment between 1150 and 1230 $^{\circ}\text{C}$ (2100 and 2250 $^{\circ}\text{F}$) for 4 h dissolves these eutectic colonies, redistributing much of the carbon.

Porosity. It is important to minimize the porosity in castings because the pores serve as initiation sites for fracture, especially fatigue cracks. There are three primary sources of porosity in superalloy investment castings: undissolved gas, microshrinkage caused by poor feeding between dendrites, and macroshrinkage caused by inadequate gating. Undissolved gas is gas that has come out of solution but, with today's vacuum technology, it is seldom experienced. Usually made up of oxygen, nitrogen, or hydrogen, this gas can form spherical voids up to two or more times the diameter of the dendrite arm spacing. Gas porosity can be essentially eliminated by maintaining a vacuum during remelting and casting.

Microshrinkage (microporosity) is inherent to castings that experience dendritic solidification. The pores are spherical, but they typically have a diameter less than the dendrite spacing. Microshrinkage forms just ahead of the advancing solidus interface because liquid metal feeding is impeded by the tortuous path through and around the secondary dendrite arms (a fluid flow problem).

The 2 to 6% shrinkage experienced upon solidification by superalloy castings makes macroshrinkage (solidification shrinkage) a problem. This type of porosity tends to be confined within the thickest section of the casting, where the last solidification takes place.

The investment caster can control solidification shrinkage to a great extent by gating or feeding those areas that are the last to solidify. With complex geometries and the desire to produce net-shape castings, the size and placement of gating is based on experience, which necessitates experimentation before the process can be defined. Modeling with computers, however, is changing this practice. Recently, it has become possible to model the solidification process of simple castings by taking into account the thermal properties of the metal and the shell. Thus, the areas of solidification shrinkage can be predicted. Once the shrinkage areas are located, various gating schemes can be evaluated until the shrink within the part is pulled into the gate. At this point, the model is verified by an experiment, significantly reducing the overall time it takes to design gating configurations. More information on the use of modeling to predict solidification shrinkage and other casting variables is available in the Section "Computer Applications in Metal Casting" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Grain Size. The control of grain size is an important means for developing and maintaining both physical and mechanical properties. Generally, a number of randomly oriented equiaxed grains in a given cross section is preferred to provide consistent properties, but often this is difficult to achieve in thin sections. To meet this objective, mold facecoat nucleants, mold and metal temperature, and other parameters are chosen to accelerate grain nucleation and solidification.

Finer grain size generally improves tensile, fatigue, and creep properties at low-to-intermediate temperatures (Fig. 10, 11, 12). The finer grain size produced by relatively rapid solidification is accompanied by a finer distribution of γ' particles and a tendency to form blocky carbide particles. The latter morphology is preferred to the script-type carbides produced by slow solidification rates, particularly for a fatigue-sensitive environment. Under these conditions, the carbide particles do not contribute to superalloy properties. As the service temperature increases, they impart important grain-boundary strengthening, provided that continuous films or necklaces are avoided.

Fig. 10 Influence of casting variables on intermediate-temperature (760 °C, or 1400 °F, at 690 MPa, or 100 ksi) stress-rupture properties of a cast nickel-base superalloy. Pour temperature and mold temperature affect solidification and thus grain size of the component. Source: Ref 19

Fig. 11 Effect of grain size control and HIP processing on the strain-controlled (axial) low-cycle fatigue of CM 247 LC

Fig. 12 Influence of grain refinement on fatigue crack growth rate. Source: Ref 19

For high-temperature rupture performance, slower solidification and cooling rates are preferred to coarsen both the grain size during solidification and the γ' precipitated during cooling. While this benefits high-temperature strength through a reduction in grain-boundary content, more property scatter can be expected due to (random) crystallographic orientation effects. For turbine blades, the desired microstructure is difficult to achieve because the thin airfoils operating at the highest temperatures should have coarse grains, and the heavier-section root attachment area, being less rupture dependent, should have a fine-grain microstructure. Where conventional practice fails, a gate, or gutter, along the airfoil edges may be employed, through which metal is caused to flow, thereby creating deliberate hot spots to retard the local solidification rate.

A significant foundry advancement has been the development of processes to produce fine-grain superalloy castings. In the late 1960s, experiments were conducted on a grain refinement technique for integral turbine wheels. The technique used the mechanical motion of a mold to shear dendrites from the solidifying metal. These dendrites then acted as nucleation sites for additional grains. However, the process was not commercially introduced because it produced castings with unacceptable levels of porosity.

In the mid-1970s, developmental work on this process resumed when it was realized that hot isostatic pressing could be used to eliminate residual casting porosity. The Howmet Corporation process that developed from this work, known as Grainex, results in ASTM grain sizes as fine as No. 2. A further Howmet Corporation development, the Microcast-X process, has led to a greater refinement in grain size (ASTM No. 3 to 5). Figure 13 compares the microstructures of grain-

refined rotors with those of a conventionally cast part. References 21, 22, 23, 24, 25 provide additional information on grain size control/property relationships and on fine-grain casting process development work performed by others in the precision investment casting industry.

Postcasting Processing

Heat Treatment. The heat treatment of cast superalloys in the traditional sense was not employed until the mid-1960s. Before the use of shell molds, the heavy-walled investment mold dictated a slow cooling rate with its associated aging effect on the casting. As faster cooling rates with shell molds developed, the aging response varied with section size and the many possible casting variables. These factors, coupled with significant γ' alloying additions, provided the opportunity to minimize property scatter by heat treatment. The combination of hot isostatic pressing plus heat treatment has also greatly enhanced properties.

Generally, heat treating cast superalloys involves homogenization and solution heat treatments or aging heat treatments. A stress-relief heat treatment may also be performed in order to reduce residual casting, welding, or machining stresses. Detailed information can be found in Ref 20.

Cast cobalt-base superalloys are not usually solutioned. However, they may be given stress relief and/or aging treatments. When required, aging is generally done at 760 °C (1400 °F) to promote the formation of discrete Cr_{23}C_6 particles. Higher-temperature aging can result in acicular and/or lamellar precipitate formation.

Cobalt-base alloy heat treatment may be done in an air atmosphere unless unusually high-temperature treatments are required, in which case vacuum or inert gas environments are used. Conversely, nickel-base alloys are always heat treated in a vacuum or in an inert gas medium.

Polycrystalline cast nickel-base superalloys may or may not be given solution treatment. Because alloys respond differently to γ' solutioning, some are given only aging treatment. For those that do respond to partial solutioning, the treatment is performed at a temperature safely below the alloy's incipient melting point, for times ranging from 2 to 6 h at temperature. Rapid cooling from high temperature is necessary to ensure that the γ' precipitate is fine sized, thereby maximizing strength potential.

Solution heat-treating procedures must be optimized to stabilize the carbide morphology. High-temperature exposure may cause extensive carbide degeneration, resulting in grain-boundary carbide overload and compromised mechanical properties. Many polycrystalline materials are used in the as-cast plus aged condition.

A typical aging cycle involves heating to 980 °C (1800 °F), holding for 5 h, and air cooling, followed by heating to 870 °C (1600 °F), holding for 20 h, and air cooling. An alternative is heating to 1080 °C (1975 °F), holding for 4 h, and air cooling, followed by heating to 870 °C (1600 °F), holding for 20 h, and air cooling. The 980 °C (1800 °F) and 1080 °C (1975 °F) exposures are carried out in conjunction with protective coating diffusion treatments. It is important that the cooling rate from the 980 °C (1800 °F) and 1080 °C (1975 °F) treatments be rapid to maintain the optimum γ' size. However, a furnace cool from 870 °C (1600 °F) treatment is acceptable.

Hot Isostatic Pressing. Hot isostatic pressing (HIP) subjects a cast component to both elevated-temperature and isostatic gas pressure in an autoclave. The most widely used pressurizing gas is argon. For the processing of castings, argon is applied at pressures between 103 and 206 MPa (15 and 30 ksi), with 103 MPa (15 ksi) being the most common. Process temperatures of 1200 to 1220 °C (2200 to 2225 °F) are common for polycrystalline superalloy castings.

When castings are hot isostatically pressed, the simultaneous application of heat and pressure virtually eliminates internal voids and microporosity through a combination of plastic deformation, creep, and diffusion. The elimination of internal defects leads to improved nondestructive testing ratings, increased mechanical properties, and reduced data scatter (Fig. 14 and 15).

Fig. 14 Effect of hot isostatic pressing on stress-rupture properties of cast IN-738. Test material was hot isostatically pressed at 1205 °C (2200 °F) and 103 MPa (15 ksi) for 4 h. (a) Test conditions: 760 °C (1400 °F) and 586 MPa (85 ksi). (b) Test conditions: 980 °C (1800 °F) and 152 MPa (22 ksi). Source: Howmet Corporation

Fig. 15 Improvement of fatigue properties by the elimination of microporosity through HIP processing. Source: Ref 19

In the past 15 years, hot isostatic pressing has become an integral part of the manufacturing process for high-integrity aerospace castings. The growth of hot isostatic pressing has paralleled the introduction of advanced nickel-based superalloys and increasing complex casting designs, both of which tend to increase levels of microporosity. In addition, to optimize mechanical properties, turbine engine manufacturers have become more stringent in allowances for microporosity. The requirement for reduced porosity levels and increased mechanical properties has been achieved in many cases through the use of hot isostatic pressing.

In selecting HIP process parameters for a particular alloy, the primary objective is to use a combination of time, temperature, and pressure that is sufficient to achieve closure of internal voids and microporosity in the casting. There are

also material considerations for avoiding such deleterious effects as incipient melting, grain growth, and the degradation of constituent phases such as carbides.

If encountered, incipient melting can be avoided by pre-HIP homogenization heat treatments or by lowering HIP temperatures. If the temperature is lowered, an increase in processing pressure may be required to obtain closure in certain alloys. For example, hafnium-bearing nickel-base superalloys such as C 101 and MAR-M 247, when cast with heavy sections (for example, integral wheels), have been found to undergo incipient melting when hot isostatically pressed at 1205 °C (2200 °F) and 103 MPa (15 ksi) for 4 h. To prevent incipient melting and still obtain closure, the HIP parameters were changed to 1185 °C (2165 °F) and 172 MPa (25 ksi) for 4 h. This trade-off between temperature and pressure can also be used to prevent grain growth and to prevent or limit carbide degradation while obtaining closure of microporosity.

Time at temperature and pressure will obviously affect processing cost. For most alloys, 2 to 4 h is sufficient. Exceptions are massive section sizes, which require additional thermal soaking time.

Introduction

THE PRIMARY GOALS in the continuing development of the aircraft gas turbine are increased operating temperatures and improved efficiencies. A more efficient turbine is required to achieve lower fuel consumption. Higher turbine inlet temperature and increased stage loading result in fewer parts, shorter engine lengths, and reduced weight. Engine operating costs can be reduced if higher temperatures are possible without increasing part life-cycle costs.

Critical turbine components include high-pressure turbine blades, vanes, and disks. During the last 15 years, turbine inlet temperatures have increased by 278 °C (500 °F). About half of this increase is due to a more efficient design for the air cooling of turbine blades and vanes, while the other half is due to improved superalloys and casting processes (Ref 1). The cooling that is now possible with serpentine cores and multiple shaped-hole film cooling (Fig. 1) enables high-pressure turbine blades and vanes to operate with turbine inlet temperatures of typically 1343 °C (2450 °F), which is above the melting point of the superalloy materials. Turbine inlet temperatures as high as 1571 °C (2860 °F) are current parameters for several advanced fighter engines (Ref 2). It is forecast that by the mid to late 1990s, fabricated single-crystal airfoils with ultra-efficient transpiration cooling schemes will be capable of operating in gas temperatures greater than 1649 °C (3000 °F) with sufficient durability and reliability for man-rated flight turbine engines. These advanced superalloy single-crystal diffusion-bonded airfoils will present a major challenge to the emerging ceramic composite component technology.

Fig. 1 Shaped holes, turbulators, pin fins, and other techniques used in turbine rotor blade cooling

For the past 28 years, high-pressure turbine blades and vanes have been made from cast nickel-base superalloys. The higher-strength alloys are hardened by a combination of approximately 60 vol% γ' [$\text{Ni}_3(\text{Al,Ti})$] precipitated in a γ matrix, with solid-solution strengthening provided by the powerful strengtheners tantalum, tungsten, and molybdenum. The γ phase, which has an ordered face-centered cubic structure, is coherent with the γ matrix, their lattice parameters being almost identical (<1% mismatch). This allows homogeneous nucleation of the precipitate with low surface energy and long-time stability at temperature, ensuring the potential usefulness of the alloys at elevated temperatures up to 0.85 T_m (melting point) for extended periods of time. Tantalum, tungsten, and hafnium substitute for some of the aluminum and titanium in the γ' , thus stiffening this phase because of their relatively large atomic size. Initially, the blades were made as

isotropic polycrystal or equiaxed castings. Under aerospace turbine engine operating conditions, failure of these equiaxed-grain components usually occurred at the grain boundaries from a combination of creep, thermal fatigue, and oxidation.

Development of the directional solidification (DS) casting process to produce blades and vanes with low-modulus (100)-oriented columnar grains aligned parallel to the longitudinal, or principal-stress, axis (Fig. 2) resulted in significant improvements in creep strength and ductility as well as in thermal fatigue resistance (5× improvement). Pratt and Whitney Aircraft (PWA) pioneered this process (Ref 3, 4), as well as its turbine engine application, and has accumulated 18 years of production experience with over 25 million flight hours with DS blades and vanes (Ref 5).

Fig. 2 Directionally solidified turbine blade CM 247 LC

There has been recent interest in DS blades not only for small- to medium-size airfoils for industrial turbines that burn natural gas but also for large base-load electricity-generating machines. Improved fuel efficiency requirements, along with the desire for high-temperature exhaust gases from the gas turbine (to produce steam suitable for co-generation electricity production), have resulted in the development and application engineering of DS blades with component lengths in the range of 305 to 635 mm (12 to 25 in.).

Single-crystal (SX) casting technology was pioneered in the mid-1960s by PWA (Ref 5, 6). However, there was limited interest in the development of single-crystal blades because the conventional heat treatments being applied to MAR-M 200-type single-crystal components did not produce improvements in creep strength, thermal fatigue strength, and oxidation resistance that significantly exceeded the results achieved with the DS columnar-grain MAR-M 200 Hf. Only ductility and transverse creep resistance were improved. Around 1975, the beneficial role of γ' solutioning heat treatment applied to DS MAR-M 200 Hf was shown by PWA (Ref 7). It was found that creep strength was a direct

function of the volume fraction of solutioned and reprecipitated fine γ' (Fig. 3). Experimental work by PWA showed that the elimination of grain-boundary strengthening elements (boron, hafnium, zirconium, and carbon) resulted in a substantial increase in the incipient melting temperature of the alloy (Ref 6). Consequently, the complete solutioning of the γ' phase, with appreciable solutioning of the γ - γ' eutectic phase, became possible without provoking incipient melting of the alloy.

Fig. 3 Rupture life versus volume fraction of fine γ' at a fixed total amount of fine and coarse γ' for DS MAR-M 200 Hf alloy

Single-crystal alloy PWA 1480 (Table 1) offered a 25 to 50 °C (45 to 90 °F) temperature capability improvement in terms of time-to-1% creep, compared to the extensively used DS MAR-M 200 Hf alloy (Ref 5). The creep property improvement, which increases with temperature, depended on optimized single-crystal microstructures with full solutioning of the as-cast coarse γ' . The PWA 1480 alloy was developed to utilize the relatively low thermal gradient, single-crystal casting facilities already available as DS production units, without the freckling problems of alloy 444 (single-crystal MAR-M 200 with no carbon, boron, hafnium, zirconium, or cobalt) (Ref 5). Alloy PWA 1480, with its high tantalum (12%) and low tungsten (4%) contents, proved to be unique with this castability feature. Multistep homogenization/solutioning treatments with tight temperature control were developed to completely solution the γ' PWA 1480 without inducing incipient melting. Since 1982, PWA has had more than 5 million flight hours of successful experience using turbine blade and vane parts of single-crystal alloy PWA 1480 in commercial and military engines (Ref 8).

Directionally solidified and single-crystal superalloys and process technology are contributing to significant advances in turbine engine efficiency and durability. Further appreciable gains are forecast, particularly from single-crystal technology over the next 10 years. These gains are expected to arise from the development of higher creep strength and improved oxidation-resistant SX alloy compositions as well as from the development of SX casting and fabrication technology to utilize advanced transpiration-cooling schemes.

Directionally Solidified Superalloys

Chemistry and DS Castability. Early work with directionally solidified columnar-grain turbine blades in the 1960s involved the superalloys used for conventionally cast, equiaxed blades containing approximately 60 vol% γ' , such as IN 100 and MAR-M 200. The problems encountered ranged from little longitudinal stress-rupture improvement with IN 100 to the lack of transverse ductility and DS grain-boundary cracking with MAR-M 200.

Pioneering work by Martin Metals resulted in the addition of hafnium to conventionally cast equiaxed superalloys to improve 760 °C (1400 °F) stress-rupture ductility and castability. For directional solidification, PWA added hafnium to MAR-M 200, which reduced DS grain-boundary cracking and increased transverse ductility. Although hafnium levels of up to 2% and greater in MAR-M 200 Hf combatted DS grain-boundary cracking, increasing levels of hafnium also increased the DS airfoil component rejection rate and the number of quality assurance problems. This was due to the occurrence of HfO inclusions that usually resulted from hafnium-ceramic reactions (core, shell-mold). Other first-generation DS alloys that were successfully and extensively adopted by turbine engine companies included René 80H (René 80 + Hf) by GE, MAR-M 002 by Rolls-Royce, and MAR-M 247 by Garrett. Both MAR-M 002 and MAR-M 247 were originally developed by Martin Metals to contain hafnium for optimized equiaxed turbine blade mechanical properties and castability. The nominal compositions of these first-generation DS superalloys are listed in Table 2. Directionally solidified superalloy turbine blades employed in large commercial turbofan engines for long-distance flights have been used for up to 15,000 h with high reliability.

Table 2 First-generation DS superalloys with extensive turbine engine airfoil applications

Continuing improvements in airfoil cooling techniques have usually led to significant gains in gas turbine operating efficiencies. However, these cooling techniques often result in very complex cored, thinwall (0.5 to 1 mm, or 0.02 to 0.04 in.) airfoil designs, which can be susceptible to grain-boundary cracking during the DS casting of high-creep-strength alloys, particularly with modern high-thermal-gradient casting processes. Thus, the need for improved DS castability resulted in the development by the Cannon-Muskegon Corporation of CM 247 LC, a second-generation alloy from the MAR-M 247 composition (Ref 9). The nominal composition of this superalloy, which is also known as René 108, is given in Table 3. The CM 247 LC alloy has particularly excellent resistance to DS grain-boundary cracking and is capable of essentially 100% γ' solutioning to maximize creep strength without incipient melting or deleterious M_6C platelet formation upon subsequent high-temperature stress exposure, but with adequate transverse ductility retention.

Table 3 Second-generation DS and SX superalloys

With respect to DS grain-boundary cracking, zirconium and silicon are generally known to be bad actors. Small amounts of a brittle, hafnium-rich eutectic phase containing high concentrations of zirconium and silicon have been found in DS crack-prone tests (Ref 9). It was observed that very small reductions in zirconium and titanium contents, combined with a very tight control of silicon and sulfur, dramatically reduced the DS grain-boundary cracking tendency of a high-creep-strength superalloy such as MAR-M 247 (Ref 11). The major microstructural effect of the lower titanium content in CM 247 LC, compared to MAR-M 247, is to significantly reduce the size of the γ/γ' eutectic nodules as well as to lower the volume fraction of the eutectic from approximately 4 vol% in MAR-M 247 to 3 vol% in CM 247 LC DS components. This factor is also believed to be significant in reducing the DS grain-boundary cracking tendency of CM 247 LC.

Heat Treatment and Mechanical Properties. Multistep solutioning techniques based on a slow temperature increase between steps and temperatures up to 1254 °C (2290 °F) are used to supersolution heat treat CM 247 LC DS airfoil components to attain microstructures such as those shown in Fig. 4. Resultant stress-rupture property improvements are illustrated in Fig. 5.

Fig. 5 Larson-Miller stress-rupture strength of DS CM 247 LC versus DS and equiaxed MAR-M 247. MFB, machined from blade; GFQ, gas fan quenched; AC, air cooled

The advent of single-crystal technology is not likely to preempt the need for DS airfoil components in the intermediate term. Directionally solidified airfoils will continue to be used for vane segments and low-pressure blades in advanced turbine engines because of the producibility of the components, which makes them cost effective.

Several third-generation DS superalloys containing rhenium have been developed that have stress-rupture strength values close to those of the first-generation single-crystal alloys (Ref 12). These new alloys are particularly useful for DS vanes where load-bearing capability, such as to support a bearing, is an important design consideration.

Single-Crystal Superalloys

The greatest advance in the metal temperature capability of turbine blades in the last 25 years has been the single-crystal superalloy and process technology pioneered by PWA (Fig. 6 and 7). The dramatic improvement in the durability of the f-100 fighter engine turbine, as evidenced by the service performance of the f-220 version, is largely due to the PWA 1480 superalloy single-crystal first-and second-stage blades and vanes (Fig. 8).

Fig. 7 Progress in turbine airfoil metal temperature capability. Source: Ref 13

Fig. 8 f-100 paired single-crystal vane cast in PWA 1480

Other pioneering single-crystal alloy development work resulted in the derivation of several single-crystal compositions from MAR-M 247 during the Garrett/NASA Materials for Advanced Technology Engines (MATE) program, which began in 1977 (Ref 14, 15). The two alloys studied extensively were NASAIR 100 and NASAIR Alloy 3; the latter contained a minor hafnium addition.

The compositions of the first-generation single-crystal superalloys, many of which are being used in turbine engine applications, are shown in Table 1: René N-4 developed by General Electric (Ref 16); SRR 99 and RR 2000 by Rolls-Royce plc (Ref 17); AM1 by the Office National d'Etudes et de Recherches Aérospatiales (ONERA) and Snecma (Ref 18); and CMSX-2, CMSX-3 (Ref 19), and CMSX-6 (Ref 20) by Cannon-Muskegon Corporation. These alloys are characterized by approximately the same creep-rupture strength (density corrected) but have differing SX castabilities, grain qualities, solution heat treatment windows, propensities for recrystallization upon solution treatment, environmental oxidation and hot corrosion properties, and densities. Typical stress-rupture properties are shown in Fig. 9 and 10.

Chemistry and SX Castability

Alloy CMSX-2 was developed in 1979 from the MAR-M 247 composition using some of the experience of the Garrett/NASA MATE program (Ref 14). A multidimensional development approach was used to achieve a high level of balanced properties (Fig. 11). The chemistry modifications applied to MAR-M 247 to develop CMSX-2 (Table 1) are summarized below with respect to function and objectives:

- Grain-boundary strengthening elements (boron, hafnium, zirconium, and carbon) were removed to achieve a very high incipient melting temperature (1335 °C, or 2435 °F)
- Partial substitution of tantalum for tungsten (CMSX-2 has 6% Ta) for good single-crystal castability, high γ' volume fraction (68%), improved γ' precipitate strength, microstructural stability (freedom from α -tungsten and tungsten, molybdenum-rich μ phases), good oxidation resistance, and coating stability
- Cobalt maintained to increase solid solubility and microstructural stability
- Chemistry balance designed to ensure a wide and practical solution heat treatment temperature range, or window (difference between the γ' solvus and the incipient melting temperature), of at least 22 °C (40 °F)
- Phacomp control of the chemistry of the alloy to avoid the occurrence of deleterious topologically close-packed phases

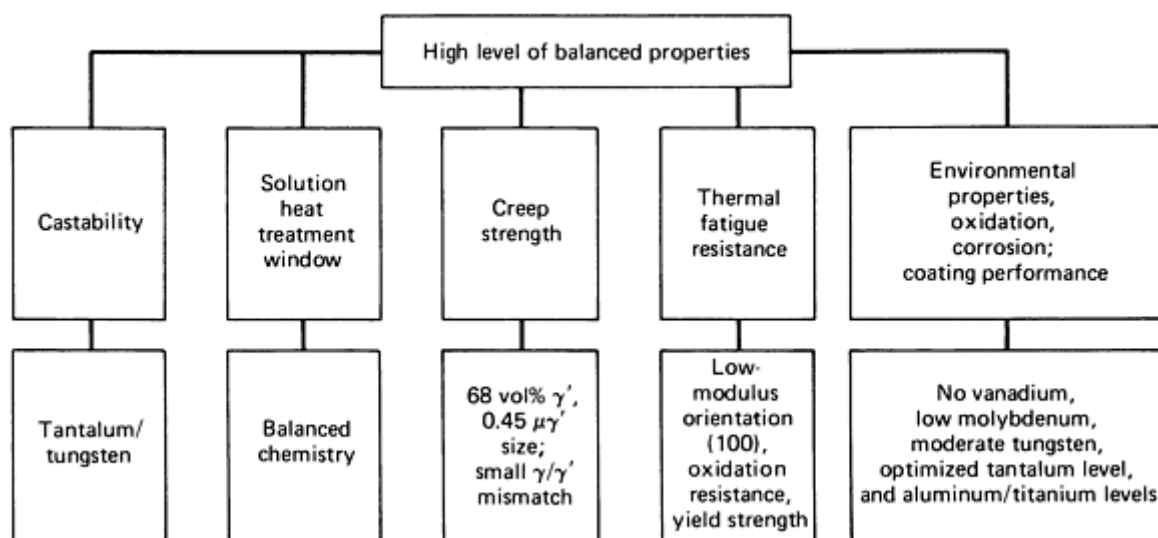

Fig. 11 CMSX-2 alloy development goal

Figure 12 shows the relative potency of tantalum, tungsten, and molybdenum as solid-solution strengtheners in binary nickel alloys, where tantalum is the most powerful strengthener on an atomic percent basis. An increase in the lattice parameter of the γ phase due to alloy additions increases the solid-solution strengthening. Tantalum also partitions strongly to the γ' phase, increasing the volume fraction and stiffening the γ' due to its relatively large atomic size. The strength of the γ' phase is important in superalloys with a high volume fraction of γ' (>50%) because γ' shearing is the primary strengthening mechanism. With the mean free edge-to-edge distance in the γ matrix between the precipitates

being smaller than the average precipitate size itself, dislocation shearing of the γ' particle is favored over Orowan dislocation looping around the γ' particles.

Fig. 12 Influence of alloying elements on the lattice parameter of binary nickel alloys. Source: Ref 21

Detailed transmission electron microscopy studies of dislocation movement in cast high-strength superalloys, such as MAR-M 002 (Table 2) and its single-crystal derivative SRR 99 (Table 1), have shown the importance of ensuring that the antiphase boundary (APB) energy is high, so that the stacking fault mode of creep deformation occurs at temperatures up to 850 °C (1562 °F), thus ensuring high creep strength (Ref 17). Tantalum additions raise the APB energy relative to the stacking fault energy (Ref 17), leading to the increased tendency for stacking faults to be formed at lower temperatures.

The CMSX-2 alloy is designed to provide good SX foundry performance because castability is a crucial alloy performance criterion for any complex, thin-wall turbine blade or vane component, a characteristic sometimes given

limited attention in alloy design. It affects not only the yield and cost of components but also the defect level and therefore component performance. Single-crystal casting defects of concern are:

- *Freckling*: A spiral of equiaxed grains caused by elemental segregation in the liquid state
- *Slivers*: Moderate-angle grain defects
- *Microporosity*: A uniform distribution of interdendritic micropores
- *Spurious grains*: High-angle grain boundaries
- *Stable oxide inclusions*: Al_2O_3
- *Carbides*: TiC

The partial substitution of tantalum for tungsten in the CMSX-2 alloy, compared to the MAR-M 247 chemistry, helps overcome the freckling problems inherent in the low-tantalum, high-tungsten single-crystal alloys. The strong γ' -forming elements, aluminum and titanium, which are also low density, tend to segregate to the last liquid to solidify in the interdendritic spaces during the SX solidification process. This can create density changes and consequential flow in the liquid metal close to the solidification front, which can nucleate freckle trails of equiaxed grains. This can occur particularly under conditions of low or changing thermal gradients. Tantalum, which is a strong γ' -forming element of high density, also tends to segregate to the last liquid to solidify in the interdendritic spaces and thus evens out these density changes in the liquid, or mushy, zone and reduces freckling tendencies.

Several studies undertaken in the United States, Europe, and Japan confirm that high [N] and [O] levels in single-crystal superalloy ingot adversely affect SX casting grain yield, supporting the importance for low [N] and [O] levels in the master alloy. Carbon, sulfur, and [O] master alloy impurities are shown to transfer nonmetallic inclusions, such as Al_2O_3 , (Ti,Ta) C/N, and (Ti,Ta)_x S, to SX parts (Ref 22). Grain defects can nucleate on these inclusions.

Several second-generation, rhenium-containing, single-crystal superalloys have been developed for turbine engine applications. Two typical compositions are given in Table 3. Rhenium partitions mainly to the γ matrix; this retards coarsening of the γ' -strengthening phase and increases γ/γ' misfit (Ref 23). Atom-probe microanalysis of rhenium-containing modifications of the PWA 1480 and CMSX-2 alloys reveals the occurrence of short-range order in the matrix with small rhenium clusters (~ 1.0 nm, or 10 \AA , in size) detected in the γ in the alloys (Ref 24). The rhenium clusters can act as more efficient obstacles against dislocation movement compared to isolated solute atoms in the γ solid solution; therefore, they play a significant role in improving the creep strength. The Larson-Miller stress-rupture comparison of CMSX-4 and CMSX-2/3 is shown in Fig. 13. The stress-rupture temperature capability advantage of CMSX-4 over CMSX-2/3 is 27 °C (48 °F) (density corrected) in the 248 MPa/982 °C (36 ksi/1800 °F) region. In the 103 MPa/1121 °C (15 ksi/2050 °F) region, the stress-rupture temperature capability advantage is 30 °C (54 °F) (density corrected). The data also indicate that CMSX-4 has a potential peak-use temperature under stress of at least 1149 °C (2100 °F).

Fig. 13 Larson-Miller stress-rupture strength of CMSX-4 versus CMSX-2/3

Single-Crystal Casting Techniques. A variety of single-crystal airfoil component-casting techniques have been developed to production status around the world in the last 10 years. Most involve a withdrawal-type vacuum induction casting furnace with mold susceptor heating. Cooling plate sizes range in diameter from 140 to 610 mm ($5\frac{1}{2}$ to 24 in.). Some of the developed SX casting techniques are presented in Ref 12, 13, 25, and 26.

The modern helicopter engine turbine vane shown in Fig. 14 represents a difficult cored configuration. The large shrouds and core make this vane susceptible to shrinkage, grain nucleation, and recrystallization during solution heat treatment. Single-crystal casting processes developed by the Allison Gas Turbine Division of General Motors Corporation result in high yields for this vane in CMSX-3. Similar yields have been demonstrated with CMSX-4 using the same Allison casting process.

Fig. 14 SX turbine vane cast in CMSX-4

Single-Crystal Heat Treatment and Microstructures. With regard to solutioning, the latest multistep ramped cycles developed for single-crystal components are designed to completely solution the γ' and most of the γ/γ' eutectic without incipient melting. An additional benefit of the high-temperature cycles is the element homogenization effect, as shown in Fig. 15. Alloy CMSX-4, which is solutioned at a maximum temperature of 1321 °C (2410 °F) in commercial vacuum heat treatment furnaces, readily attains the 99%+ (<1% remnant γ/γ' eutectic) solutioned microstructure, as illustrated in Fig. 16.

Fig. 15 CMSX-2 element homogenization effect. Source: Ref 21

Fig. 16 CMSX-4 (heat VF 719) SX test of flat specimen, 25 mm wide by 1.25 mm thick by 100 mm long (1 in. by 0.05 in. by 4 in.). Specimen was cast, 99% solutioned, and double aged. Micrographs taken from longitudinal orientation. (a) 90 \times . (b) 365 \times . (c) 905 \times . (d) 905 \times

With regard to aging, the weight fraction of γ' in CMSX-2 is approximately 68% with chemistry, as shown in Table 4, both being independent of the aging treatments used. The measured lattice parameter of the γ' is 0.35865 nm (3.5865 \AA), with a γ/γ' misfit at room temperature of 0.14% (Ref 27) and -0.33% at 1050 $^{\circ}\text{C}$ (1922 $^{\circ}\text{F}$) (Ref 28).

Table 4 Chemical composition of the γ' phase in CMSX-2

Element	Composition, wt%
Nickel	69.25
Cobalt	3.15
Chromium	2.05

Molybdenum	0.30
Tungsten	7.25
Aluminum	7.55
Titanium	1.30
Tantalum	9.15

It has been reported by ONERA that a high-temperature aging heat treatment (T_2) [16 h/1050 °C (1922 °F) air cooled (AC)] following solution treatment, with subsequent intermediate temperature aging [20 h/871 °C (1600 °F) or 48 h/850 °C (1562 °F)], gives CMSX-2 cuboidal γ' with a mean size of 0.45 μm (18 $\mu\text{in.}$), which optimizes creep response (Ref 27, 29). Similar γ' morphology and size are obtained with a 4 h/1079 °C (1975 °F) AC postsolution treatment. The morphology of the γ' in CMSX-2 with this ONERA-type aging treatment is shown in Fig. 17a, which should be compared to the conventional irregularly shaped γ' particles with a mean size of 0.3 μm (12 $\mu\text{in.}$) shown in Fig. 17b. The particles shown in Fig. 17b result from a 5 h/982 °C (1800 °F) AC + 48 h/850 °C (1562 °F) aging (T_1). Specimens of the T_2 type at 760 °C (1400 °F) deform in a homogeneous manner in the early stage of creep (Fig. 18). The homogeneous nature of the deformation leads to a rapid strain hardening of the material, causing a decrease in the creep rate. The T_1 heat treatment, which produces smaller, irregular shaped particles, favors inhomogeneous deformation within the specimen due to the precipitate shearing during the early stages of creep (Fig. 19). In this case, the amplitude of primary creep is high, and the strain hardening of the material is achieved at a much later stage, compared with that of the T_2 -type heat-treated specimens.

Fig. 19 Inhomogeneous deformation in CMSX-2 (T_1 heat treatment) during primary creep at 760 °C (1400 °F). Source: Ref 29

During creep at high temperature, the γ' precipitates coarsen in the form of rafts perpendicular to the stress axis. The kinetics of raft formation depend on the testing temperature, among other factors. At 1050 °C (1922 °F) under a stress of 120 MPa (17.4 ksi), the rafts form within a few hours (Fig. 20). The rafts have a high aspect ratio in the T_2 -type heat-treated specimens in which the cuboidal γ' precipitates are already aligned. The lateral extension of the γ' phase in the form of rafts causes the specimen to creep at a much lower rate, compared with the creep rate of the material in which the γ' phase coalesces irregularly. The CMSX-2 and CMSX-3 alloys that show this type of rafted γ' morphology possess very long rupture lives at high temperatures. In these alloys, the misfit between the γ and γ' phases is found to be negative at high temperatures (Ref 30).

Fig. 20 Oriented coalescence of the γ' phase in CMSX-2 after 20 h of creep at 1050 °C (1920 °F) under 120 MPa (17.4 ksi). Tensile stress axis is [001]. Source: Ref 29

Work by ONERA and Ishikawajima-Harima Heavy Industries Company, Ltd. (IHI) shows some interesting effects of the crystal orientation and heat treatments on the creep behavior and strength of several single-crystal superalloys (Ref 31). The salient features can be summarized as follows:

- At intermediate temperatures (760 to 849 °C, or 1400 to 1560 °F), the creep behavior of nickel-base single-crystal superalloys is extremely sensitive to crystal orientation and γ' precipitate size. For a γ' size in the range of 0.35 to 0.5 μm (14 to 20 $\mu\text{in.}$), the highest creep strength is obtained near [001], while orientations near the [111]-[011] boundary of the standard stereographic triangle exhibit very short creep lives. When the γ' size decreases to 0.2 μm (8 $\mu\text{in.}$), the longest creep lives are exhibited, in decreasing order, by the crystals oriented near [111], [001], and [110]. The anisotropy in creep between the [001] and [111] orientations can therefore be reduced by appropriate precipitation heat treatments. The creep strengths, however, remain poor near the [011] orientation
- At high temperatures (982 to 1049 °C, or 1800 to 1920 °F), the creep behavior of the single-crystal superalloys is much less sensitive to crystal orientation and γ' size than it is at intermediate temperatures. The [001]-oriented single crystals develop a rafted γ' structure normal to the tensile stress axis, while the γ' precipitates coarsen irregularly in the [111] specimens

Fatigue. An important property that must be considered when selecting single-crystal superalloys for turbine blade applications is fatigue strength. Single crystals of CMSX-2 have been cast both under low- and high-gradient conditions and then subjected to high-cycle fatigue tests in the repeated tension mode at 870 °C (1598 °F) (Ref 29); the results are reported in Fig. 21. The fatigue resistance of specimens cast under a very high temperature gradient (laboratory conditions) is much superior to that of material cast under industrial conditions, primarily because of the very small pore size (<10 μm , or 40 $\mu\text{in.}$) inherent in the high-gradient specimens. The single crystals cast under industrial conditions have a more heterogeneous structure where the interdendritic spacing and the level of porosity vary along the length of the bar. Specimens corresponding to the beginning of solidification exhibit better fatigue resistance than those corresponding to the end of solidification. Some fatigue tests were also performed on specimens in which a rafted γ' morphology was developed prior to testing. It is interesting to note that the fatigue behavior is not significantly affected by the rafted γ' morphology (Ref 29).

Fig. 21 Effect of thermal gradient and heat treatments on the high-cycle fatigue behavior of CMSX-2 at 870 °C (1598 °F) with frequency of 50 Hz. Source: Ref 29

Strain-controlled, fully reversed low-cycle fatigue tests performed at 760 °C (1400 °F) confirm the much better fatigue behavior of single crystals cast under a high gradient (Fig. 22). In this type of test, the higher the deviation from the [001] orientation, the shorter the fatigue life. It can be seen in Fig. 22 that for a total strain range of 1.2%, the fatigue life is decreased by an order of magnitude when the crystal orientation, relative to the [001], moves away from 6 to 22°. The decrease in fatigue life is a consequence of the increase in stress level through the increase of elastic modulus. Because the plastic strain component at 760 °C (1400 °F) is small, the results can be plotted as total stress versus the number of cycles to failure (Fig. 22). In Fig. 22, the effect of crystalline orientation on the fatigue life of the industrially processed single crystals is not apparent, and all the results of low-gradient single crystals can be represented by a single curve.

Fig. 22 Effect of thermal gradient, orientation, and hot isostatic pressing on the strain-controlled low-cycle fatigue behavior of CMSX-2 (fully reversed, with frequency of 0.33 Hz) at 760 °C (1400 °F). Numbers represent the deviation, in degrees, from the [001] orientation. (a) Strain versus cycles to failure. (b) Stress versus cycles to failure. Source: Ref 29

An examination of fracture surfaces shows that the cracks are initiated at microporosity, which indicates that these defects (microporosity) are of primary importance in determining the fatigue life of CMSX-2. The size of microporosity in industrial single crystals can be as large as 50 to 80 μm (2000 to 3200 $\mu\text{in.}$), but is rarely more than 10 μm (400 $\mu\text{in.}$), in single crystals cast under very high temperature gradients (laboratory conditions). The adverse effect of microporosity is also confirmed by the results obtained after hot isostatic pressing [1000 bars/1315 °C (2400 °F)] CMSX-2 single-crystal bars solidified under the low-temperature gradient. The fatigue strength of single crystals cast under low gradients after hot isostatic pressing can be improved to that of the high-gradient-processed specimens (Fig. 22). The techniques developed to hot isostatic press CMSX-2 ensure that no recrystallization occurs internally within the test bars during the hot isostatic press cycle.

Oxidation and Hot Corrosion. Coatings perform well with single-crystal alloys, particularly when they are optimized to the base alloy system, as shown by the work with PWA 1480 alloy in Fig. 23. The absence of grain boundaries, rosette clusters of carbides, and elemental segregation in heat-treated single-crystal alloys contribute to improved coating performance.

Fig. 23 Coating performance of PWA 1480 at 1149 °C (2100 °F), burner rig oxidation. Source: Ref 13

Cyclic oxidation testing at 900 and 1050 °C (1652 and 1922 °F) shows uncoated CMSX-4 and CMSX-2 to have excellent and similar performance (Ref 32). This work also shows uncoated CMSX-4 to have superior molten-salt hot corrosion characteristics compared to CMSX-2, most probably because of its lower tungsten content. Ultrahigh-temperature cyclic burner rig oxidation studies undertaken by Allison at 1177 °C (2150 °F) show that uncoated, modified CMSX-3 (designated CMSX-3 Mod A) has excellent performance similar to uncoated MAR-M 247 (which contains 1.4% Hf), with little or no attack after 140 h of testing (Fig. 24). Alloy CMSX-4 Mod A has also shown similar results.

Strategic Materials Availability and Supply

Joseph R. Stephens, National Aeronautics and Space Administration, Lewis Research Center

Introduction

THE SUPERALLOYS are critical to the economic survival of the United States aerospace industry. Thus, it is imperative that the raw material resources required for superalloy production be readily available to U.S. producers. During the initial years of superalloy development, resources for iron, nickel, and to some extent chromium were available within the United States or from neighboring countries such as Canada and Cuba. However, in more recent years, superalloy compositions have become more complex, requiring ten or more different elements in a single alloy; environmental restrictions and labor costs have pushed sources offshore; and political and military changes have made resources supplies from countries that were once dependable suppliers unreliable or unavailable.

Because of these changes in the world market, superalloy producers have sought to ensure a reliable supply of imported materials. At the same time, they are exploring the suitability of alternative alloys in the event of the future unavailability of any imported alloying elements currently used in superalloys. One approach to alternative alloys is to substitute readily available elements for imported alloying elements. Obviously, this is not a simple solution because the compositions of superalloys are not only complex, their microstructures (which are dependent upon a critical balance of alloying constituents) must be maintained in order to achieve desired properties.

Because of shortages or limited availability of alloying elements over the years, for example, cobalt in the 1950s, chromium in the 1970s, and cobalt and other elements in the late 1970s and early 1980s, the Lewis Research Center of the National Aeronautics and Space Administration (NASA) undertook a program to address this continuing problem. This article reviews some of the trends in superalloy development; defines the term strategic materials; summarizes the current status of U.S. resources and reserves; discusses the supply sources and availability of strategic materials; and, finally, concentrates on the results achieved by the NASA Conservation of Strategic Aerospace Materials (COSAM) program (Ref 1).

Strategic Materials Availability and Supply

Joseph R. Stephens, National Aeronautics and Space Administration, Lewis Research Center

Reserves and Resources

As already stated, a thriving superalloy industry within the United States requires a readily available supply of alloying ingredients. The ideal situation would be for U.S. mining companies to act as primary suppliers to the alloy producers. Unfortunately, the United States does not have ample reserves and resources for some required alloying elements and therefore has become more and more dependent on foreign sources for a number of strategic materials.

Planning for future aerospace materials needs requires an assessment of U.S. reserves and resources. The principal distinction between reserves and resources is that reserves are based on current economical availability. They are known, identified deposits of mineral-bearing rock from which mineral(s) can be extracted profitably with existing technologies and under current economic conditions. On the other hand, resources include not only these reserves, but other mineral deposits that may eventually become available. The latter can be either known deposits that are not economically or technologically recoverable at present or unknown deposits that have not yet been discovered, but whose existence may have been inferred (Ref 2, 3).

Table 1 summarizes the estimated reserve and resource status of the United States for 18 metals. The United States ranks first for molybdenum reserves and second for copper. In comparison, the U.S.S.R. ranks either first or second for 8 of the 18 metals, and South Africa ranks either first or second for 5 of the 18. The U.S. domestic position presented in Table 1 and supported by further information indicates negligible reserves of chromium, cobalt, niobium (columbium), tantalum, and manganese, all vital to the aerospace and steel industries.

(b) Bauxite.

Although the United States does not have reserves of a number of elements, it is nonetheless a leading producer because it imports the necessary minerals and converts them into metals and alloys. Table 2 shows that the United States ranks first or second in 6 metals: aluminum, copper, magnesium, molybdenum, titanium, and rhenium. The U.S.S.R. holds this favorable position in 12 metals: rhenium, iron, manganese, nickel, aluminum, magnesium, titanium, tungsten, vanadium, gold, chromium, and platinum.

One other important consideration is the domestic consumption and production of the metals needed for the U.S. economy. Table 3 gives information on this factor for all 18 elements. It should be noted that in 1988 foreign purchases were required for the four elements (chromium, cobalt, niobium, and tantalum) designated as strategic metals in the COSAM program, as well as for manganese and nickel. In contrast, there is a fairly good matchup of production and consumption for iron, aluminum, copper, magnesium, titanium, and rhenium, and molybdenum production greatly exceeds consumption.

Table 3 United States production and consumption in 1988

Strategic Materials

The United States has adequate supplies of metals such as copper, iron, and molybdenum. Stable/friendly foreign countries are sources for others, for example, nickel (Canada), titanium (Australia for rutile), aluminum (Jamaica, for bauxite), and tungsten (Canada) (Ref 5). However, by examining our import dependence on other metals, as shown in Fig. 1, it is apparent that we are a have-not nation for many important metals. Of particular concern is the aerospace industry because it is highly dependent on imports for several key metals that are considered strategic materials. For the purposes of this article, strategic materials are defined as predominately or wholly imported metals that are contained in the alloys used in aerospace components that are essential to the future economic health of the U.S. aerospace industry. In the study of strategic materials, two approaches have been used to identify the strategic materials most critical to the aerospace industry, an index method and a survey method.

Fig. 1 Estimated 1988 net import reliance of selected nonfuel mineral materials as a percent of apparent consumption, where net import reliance equals imports minus exports plus adjustments for government and industry stock changes. EEC, European Economic Community

The index method was used to define a vulnerability index for metals used in superalloys. Metals of greater vulnerability were identified as strategic metals. This study was undertaken by Stalker *et al.* (Ref 6). The index described 18 metals, listed in Table 1. Each metal was ranked 21 different ways, for example, its importance in relation to U.S. needs (in a peace economy and in a war economy), in relation to U.S. reserves, and in relation to cost in dollars per pound.

An analysis of the data from this study shows that the 18 metals generally fall in three groupings. The most strategic metals have an index of about 8 or greater on a scale from 1 to 10, with 10 being the most strategic. The midgroup metals have numbers between about 5 and 8; and the least strategic metals have indexes lower than 5. The breakdown of the 18 metals is shown below:

Most strategic	Midgroup	Least strategic
Ta	V	Al
Cr	Re	Cu
Pt	Ti	Mo
Nb	W	Mg
Mn	Ag	Fe
Co	Ni	
	Au	

It should be noted that although this ranking is in order of decreasing index for each of the three groups, the absolute rank within a group can be altered by using other data, such as a more complete breakdown of resources and reserves (to be discussed later). In addition, price volatility can affect known economic reserves as well as the weighting factors used. Regardless of these variables, it is doubtful that the most strategic list will change in composition.

The output of the study, with data from all 21 categories, is summarized in Table 4. The rankings are presented in terms of peacetime and wartime scenarios, based on such factors as reserves, consumption, production costs, and recyclability, in addition to subjective judgments regarding the likelihood of a mineral cartel. Consideration of the needs of a wartime economy yielded slightly different normalized scores, but with major concern for the same 6 elements. In a further refinement, subjective weighting factors were applied to obtain a still more realistic appraisal. Weighting yielded significant increases in importance for manganese, copper, and aluminum and a decrease in importance for gold. However, the overall picture remained fairly constant. The availability and strategic nature of manganese are described in an appendix to this article.

Table 4 Strategic metals index analysis for peacetime and wartime economies

Each of the most strategic metals has special capabilities such that the U.S. economy would not function well without them. Because the United States has a very limited reserve of each, attention must be given to the dependence on foreign supplies. Each element is unique and therefore requires a careful review of its role in superalloys in order to develop short-range and long-range plans for continuing supplies.

Survey Method. The second approach to identification of the metals most strategic to the United States involved meetings with the American Society of Mechanical Engineers (ASME) Gas Turbine Panel in 1979 and a survey of aerospace companies in 1980, which led to the recognition of the need to focus primarily on the aircraft engine industry. Based on the findings of these meetings and further discussions with several aircraft engine manufacturers, four elements that were of particular concern were identified (Ref 7). The alloys used to build the critical high-temperature components for aircraft propulsion systems require the use of three refractory metals, chromium, tantalum, and niobium, plus a fourth strategic metal, cobalt. These metals are contained in superalloys used in engine compressors, turbines, and combustors and are among the six elements having the highest strategic indexes of the 18 metals evaluated in Ref 6. Although the remaining two elements were considered, along with less strategic metals, it was decided to focus on the four aforementioned metals in the NASA COSAM program.

Strategic Materials Availability and Supply

Joseph R. Stephens, National Aeronautics and Space Administration, Lewis Research Center

The Superalloys

Superalloys are the major materials of construction for today's high-temperature gas turbine engines used for both commercial and military aircraft. Nickel-base superalloys, along with iron-base and cobalt-base superalloys, are used throughout the engines in wrought, cast, powder metallurgy (P/M), and cast single-crystal forms to meet the requirements imposed by the aircraft industry.

Nickel-base superalloys were created at approximately the turn of the century with the addition of 20 wt% Cr in an 80 wt% Ni alloy for electrical heating elements (Ref 8). In the late 1920s, small amounts of aluminum and titanium were added to the 80Ni-20Cr alloy, with a significant gain in creep strength at elevated temperatures. It soon became apparent that iron and cobalt alloys could be more effectively strengthened by solid-solution additions, while nickel alloys could be strengthened by a coherent phase, γ' . Concurrent with these additions, the carbon present in the alloys was identified as having a strengthening effect when combined with other alloying elements to form M_6C and $M_{23}C_6$ carbides. Other grain-boundary formers, such as boron and zirconium, were added to polycrystalline materials to hold the material together.

In the early development time period (about 1926), Heraeus Vacuumschmelze A.G. received a patent for a nickel-chromium alloy that contained up to 15 wt% W and 12 wt% Mo, thereby introducing the refractory metals into superalloy compositions. The purpose of adding refractory metals was to increase the high-temperature strength of the nickel-base alloy. By the 1930s there were two iron-base "heat-resisting alloys" containing either tungsten or molybdenum additions, and the use of these two metals was widely accepted in cobalt-base alloys. In the early 1950s, alloys containing about 5 wt% Mo were introduced in the United States. The commercial exploitation of Mo additions took place in 1955. A cast alloy containing 2 wt% Nb was available in the late 1950s. Only one commercially significant alloy uses vanadium; it became available in about 1960. In the early 1960s, tungsten and tantalum were widely accepted for alloying in nickel-base alloys. Finally, the demonstration of the effectiveness of rhenium additions in nickel-base alloys occurred in the late 1960s.

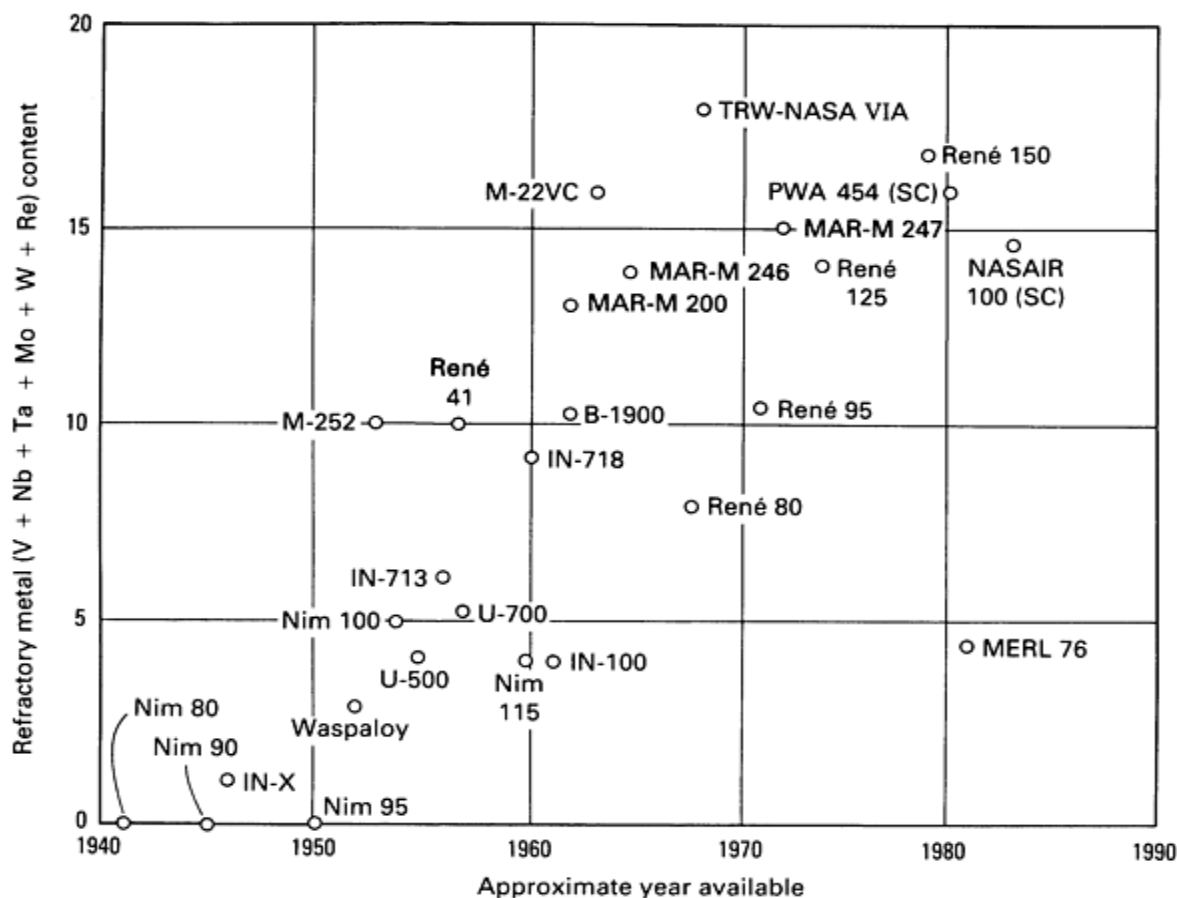

The original 20 wt% Cr level in superalloys was increased to 25 wt% or higher in some alloys to gain oxidation resistance, but because of its perceived deleterious effect on strength, chromium was reduced to as low as 10 wt% in favor of aluminum for oxidation protection (Ref 9). However, reducing chromium led to the onset of hot corrosion-enhanced oxidation resulting from sodium and sulfur in the fuel and exhaust gas stream. Ingestion of seawater spray into helicopter engines used in the Vietnam war wreaked havoc in low-chromium turbine blades, leading to a reevaluation of the use of chromium in superalloys.

The trend toward the increased use of refractory metals is shown in Fig. 2 and Table 5. It is apparent that, based on weight (Fig. 2a), the refractory metal content of nickel-base alloys tended to increase steadily from the mid-1940s to about 1980. Figure 2b shows that, based on atoms, the use of refractory metals increased from 1 to about 6 at.% in less than a decade. With this increasing use of refractory metals in superalloys, the concern for the availability of those determined to be strategic, that is, chromium, niobium, and tantalum, becomes apparent.

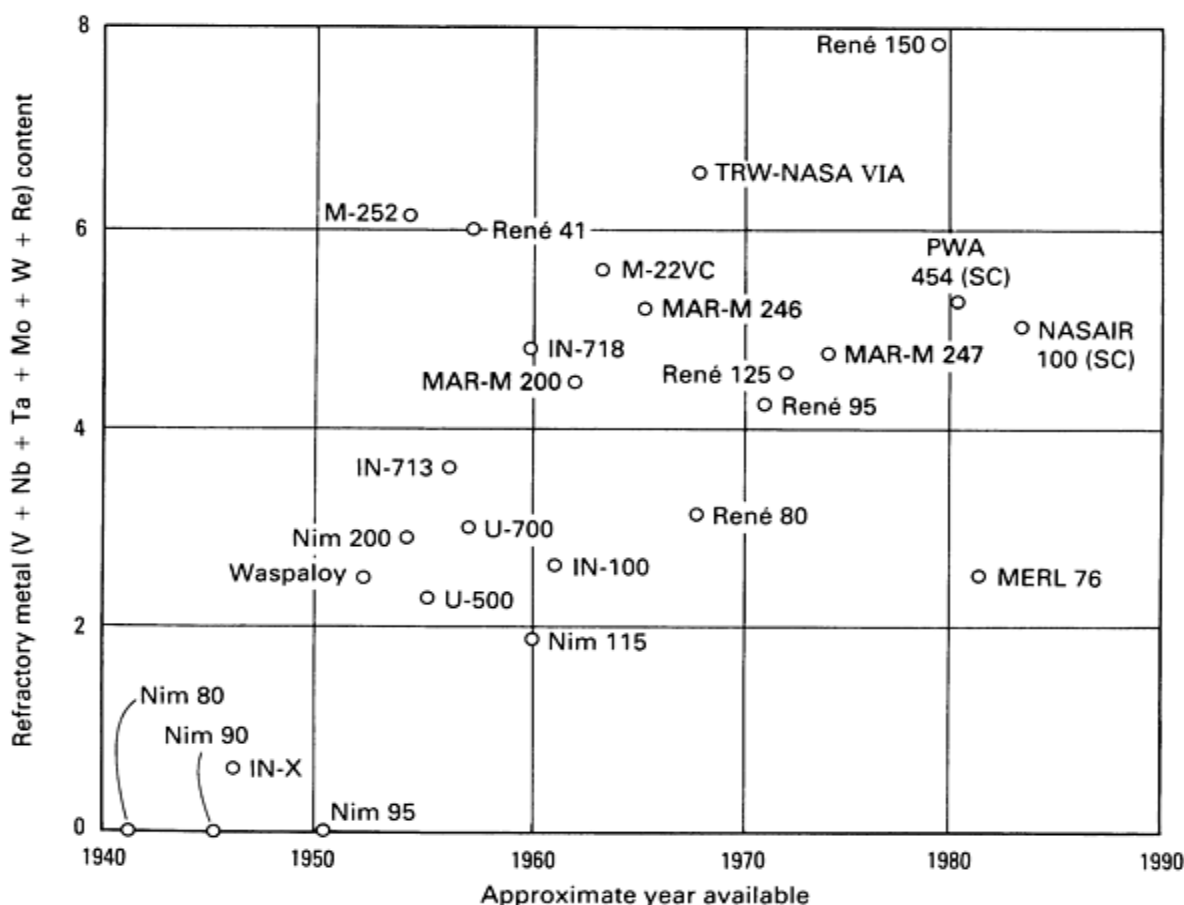

Table 5 Refractory metal content of selected nickel-base superalloys and year of availability

Cobalt is used in a variety of both cobalt-base and nickel-base superalloys. Its largest usage, in terms of pounds consumed, is in nickel-base alloys. Several nickel-base and cobalt-base superalloys are listed in Table 6, which shows the range of cobalt content in these alloys. It was the sharp rise in the cost of cobalt, more than any other factor, that brought on the need for the COSAM program. The cost of cobalt which sold for approximately \$12.15/kg (\$5.50/lb) in 1977, increased to over \$66/kg (\$30/lb) in 1979, with spot prices as high as \$121/kg (\$55/lb). As a rule-of-thumb, the price of cobalt has historically been higher than that of nickel by a factor of two to three. In 1980, that factor was in excess of seven. Primarily because of the spiraling cost of cobalt, the United States experienced a decline in cobalt use. In 1978, 9×10^6 kg (20×10^6 lb) of cobalt were consumed. In 1980, use was down to 7.3×10^6 kg (16×10^6 lb) (Ref 10). During this same time period, the use of cobalt to produce superalloys, primarily for aircraft engines, increased from 1.8×10^6 kg (4×10^6 lb) in 1978 to 3.3×10^6 kg (7.2×10^6 lb) in 1980. This proportionately high increase in cobalt use in superalloys can be attributed to the increased orders of aircraft during this time period. In 1988, of 6.8×10^6 kg (15×10^6 lb) consumed, 2.5×10^6 kg (5.6×10^6 lb) was used in superalloys. Because the well-being of the aircraft industry was considered very important, the COSAM program, as well as industry activities, was undertaken.

Table 7 presents a list of several superalloys that have been used in gas turbine engines or that are emerging as replacements because of the promise of increased operating temperatures and higher efficiencies for the aircraft of the future. These alloys are used in a variety of forms, such as turbine blades, vanes, and disks; compressor components; and ducting components, and they serve a multitude of needs. The next section of this article focuses on the NASA COSAM program and some of its results.

Strategic Materials Availability and Supply

Joseph R. Stephens, National Aeronautics and Space Administration, Lewis Research Center

COSAM Program Approach

The COSAM program had three general objectives: First, to contribute basic scientific information to the turbine engine "technology bank" in order to maintain U.S. national security in the event of constriction or interruption of strategic material supply lines; second, to help reduce the dependence of U.S. military and civilian gas turbine engines on disruptive; worldwide supply/price fluctuations in regard to strategic materials; and finally, by virtue of these research contributions, to help minimize the acquisition costs and optimize the performance of these engines in order to contribute to U.S. preeminence in world gas turbine markets.

To achieve these objectives, a three-pronged approach was undertaken, consisting of research on strategic element substitution, advanced processing concepts, and alternate materials (Ref 11). The intent was to achieve conservation, and reduced dependence on strategic metals by systematically examining the effects of replacing cobalt, niobium, and tantalum with less strategic elements in current, high-use engine alloys. This would help guide future material specifications if one or more of these metals were ever in short supply and would create a powerful base of understanding to benefit future advanced alloy development.

Conservation through advanced processing concepts research can be achieved by creating the means for using dual-alloy and multiple-alloy tailored structures that can minimize strategic material input requirements, by using them only where mandatory, and thus lowering total use.

In the long term, the development (higher risk) of readily available alternate materials to replace most strategic metals could lead to a dramatic reduction in U.S. dependence on foreign sources. The last two technologic areas could help conserve all four strategic metals: cobalt, tantalum, niobium, and chromium.

The various efforts of the COSAM program were conducted under the management of NASA Lewis Research Center, where some work was conducted in-house. In addition, there were cooperative programs between NASA Lewis, industry, and various universities in triparty projects to utilize the expertise of each and to produce synergistic results.

Typically, the research conducted at NASA involved oxidation/corrosion, low-cycle fatigue, thermal fatigue, and coatings; the research done by industry involved fabricability; and that done by universities involved mechanical properties, microstructures, and microchemistry. Varying levels of support flowed from one group to another, depending on the specific project. Highlights of the results obtained are described in the remainder of the article.

Substitution

The reduction and/or replacement of cobalt, cobalt and tantalum, tantalum, and niobium in certain alloys is described below.

Cobalt in Waspaloy and Udimet 700. Waspaloy, which contains 13% Co, is used in turbine disks. Because of the size and weight of a turbine disk, a major portion of the cobalt used in gas turbine engine components is used in this application. Udimet 700, containing 17% Co, can be used for both disks and blades, depending on the processing history and the heat treatment used.

The effects of reducing cobalt in Waspaloy are reported in Ref 12. Highlights of that study are shown in Fig. 3. Tensile strength decreased only slightly as the amount of cobalt in the alloy decreased. However, rupture life decreased substantially with decreasing amounts of cobalt. Table 8 summarizes the major findings of this study. In addition to the slight decrease in the amount of γ' (Ni_3Al , the major strengthening phase in nickel-base superalloys) in Waspaloy, the major effects that removing cobalt had on mechanical properties were attributed to a possible higher stacking fault energy of the matrix and to changes in carbide partitioning in grain boundaries.

Table 8 Effects of removing cobalt from Waspaloy

Property or characteristic	Result
Hot workability	
Heating	No change
Cooling	Decrease
Tensile strength	Slight reduction
Tensile ductility	No change
Stress-rupture life	Major decrease
Creep rate	Sixfold increase
γ' solvus temperature	No change
γ' volume fraction	Slight decrease (18-16%)
γ' chemistry	Decrease of Cr and Ti and increase of Al

Carbides	
Chemistry	More metal carbide as-rolled; more $M_{23}C_6$ 843 °C (1550 °F) aging
Morphology	Coarser

Fig. 3 Effect of cobalt content in Waspaloy on (a) rupture life at 730 °C (1345 °F) and 550 MPa (80 ksi) and (b) tensile strength at 535 °C (995 °F)

Barrett (Ref 13) examined the effect of cobalt on the oxidation resistance of Waspaloy. Results, shown in Fig. 4, indicate that, based on specific weight change data up to 1100 °C (2010 °F), cyclic oxidation resistance is essentially independent of cobalt content.

Fig. 4 Effect of cobalt on cyclic oxidation resistance of Waspaloy at 1100 °C (2010 °F) and 1 h/cycle

A further study of the reduced cobalt composition Waspaloy alloys was conducted at Purdue University by Durako (Ref 14). This investigation focused on the microstructure of the alloys and on metallographic studies of extracted γ' and carbide precipitates. The effect of the removal of cobalt in Waspaloy on mechanical properties was attributed by Durako to be due in part to the decrease in volume percent γ' , in agreement with Maurer (Ref 12); to the reduction in γ/γ' mismatch, with increasing dislocation mobility; and to an indirect increase in the matrix stacking fault energy resulting from matrix chromium depletion caused by the formation of massive $M_{23}C_6$ chromium-rich carbides. Both Durako and Maurer suggested that alloy modifications might allow the reduction or removal of cobalt from Waspaloy.

The effects of the removal of cobalt from wrought Udimet 700 alloy were studied extensively as part of a cooperative program involving Special Metals Corporation, Columbia and Purdue Universities, and NASA Lewis Research Center. Fabricability was investigated by Jackman and Maurer (Ref 12) and Sczerzenie and Maurer (Ref 15) of Special Metals Corporation, while mechanical and metallurgical properties were studied by Jarrett and Tien (Ref 16) of Columbia University. Fabricability, based on Gleeble and high strain rate tensile tests corresponding to rolling temperatures in the 1000 to 1100 °C (1830 to 2010 °F) range show no cobalt effect on high-temperature ductilities. Of particular interest is the work described in Ref 16 on the effect of the disk (partial γ' solutioning) and blade (complete γ' solutioning) heat treatments on stressrupture and creep properties. Rupture life as a function of cobalt content is shown in Fig. 5 for the two heat-treated Udimet 700 conditions. The disk heat treatment resulted in a reduction in rupture life when the cobalt content was less than 9%. In the blade heat-treated condition, specimens exhibited an increase in rupture life with decreasing cobalt content at the lower stress level and were insensitive to cobalt content at a higher stress level. Creep rates, as expected, showed similar trends with cobalt content and heat treatment (Fig. 6). The results of the work of Jarrett and Tien (Ref 16) are summarized below.

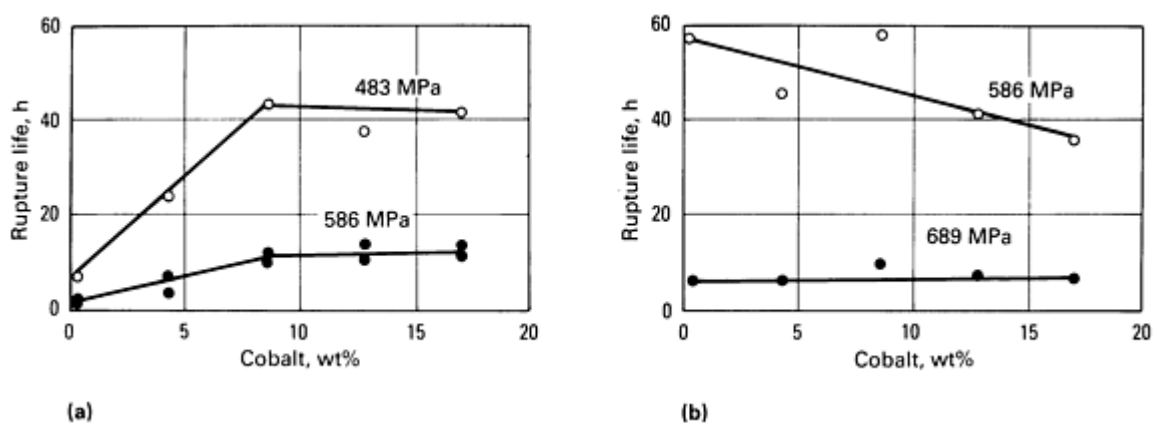

Fig. 5 Stress-rupture life of Udimet 700 at 760 °C (1400 °F) versus cobalt content. (a) Disk heat treatment. (b) Blade heat treatment

Fig. 6 Creep rates of Udimet 700 at 760 °C (1400 °F) as a function of cobalt content. (a) Disk heat treatment. (b) Blade heat treatment

Room-temperature tensile yield strength and tensile strength were only slightly decreased in the disk alloys and were basically unaffected in the blade alloys as cobalt was removed. Creep and stress-rupture resistance at 760 °C (1400 °F) were found to be unaffected by the cobalt level in the blade alloys and decreased sharply only when the cobalt level was reduced below about 9% in the disk alloys.

The microstructure was found to be very heat-treatment sensitive. After the fine grain, disk heat treatment, the fine strengthening γ' precipitates fraction decreased as cobalt was removed because of a corresponding increase in undissolved γ' fraction. No such change occurred after the higher-temperature, coarse grain heat-treatment, during which all γ' particles were initially dissolved.

Cobalt was observed through scanning transmission electron microscopy and energy dispersive spectroscopy to partition mostly to the γ matrix phase. Cobalt also changed the relative stability of the various carbides and destabilized rather than stabilized the alloy with respect to σ -phase formation after long-term aging. It did not significantly alter γ' coarsening kinetics.

The correlation of the detailed microstructural and microchemistry information with yield strength and creep rate formulas especially developed for particle-strengthened systems showed that the slight decrease in yield strength was due to γ' fraction and antiphase boundary energy considerations. The significant drop in creep and stress-rupture resistance in the low-cobalt and cobalt-free disk alloys is due to a change in the fine γ' volume fraction and is relatively unaffected by matrix composition or stacking fault energy factors.

Harf (Ref 17) of NASA Lewis conducted a parallel program on hot isostatic pressed (HIP) powder metallurgy (P/M) Udimet 700. Initial results confirmed the previous results of Ref 16 on the cast-plus-wrought (CW) material. Harf then focused on modifying the disk heat treatment to improve the creep-rupture properties of the 0% Co alloy (Ref 18).

In the original concept of comparing the properties of Udimet 700 alloys with decreased cobalt levels, the comparison was made with minimal change in the heat treatment of the various compositions. A major compromise in the disk-type heat treatments had been to adjust the partial solutioning temperature to maintain a nearly constant temperature difference from the γ' solvus, particularly in the HIP-P/M alloys. However, because the γ' solvus increased with decreasing cobalt content, this meant that the thermal gap between the partial solutioning temperature and the subsequent aging temperatures (which were the same for all cobalt contents) increased with decreasing cobalt content.

Harf (Ref 18) modified the aging temperatures to keep the thermal gap for the 0% Co alloy similarly to that used for the 17% Co Udimet 700 alloy. His results showed that this technique was successful in improving the rupture life and creep resistance of the 0% Co alloy at 650 °C (1200 °F). He attributed this improvement to the microstructure, which contained an increased quantity of ultra fine, 20 nm (200 Å) γ' particles, as shown in Fig. 7. The standard heat treatment (Fig. 7a) has fewer particles than the modified heat treatment (Fig. 7b). In the CW alloy, too, substantial improvements in creep-rupture properties were observed at 760 °C (1400 °F) as a result of a similar modification in heat treatment for the 0% Co alloy.

Fig. 7 Transmission electron micrographs comparing ultrafine particles in Udimet 700-type alloys with 0% cobalt content. (a) Standard heat treatment. (b) Modified heat treatment

Barrett (Ref 13) has also investigated the cyclic oxidation resistance of the low-and/ or no-cobalt Udimet 700 alloys. Results of this study are shown in Fig. 8. At 1100 °C (2010 °F), the removal of cobalt from Udimet 700 improved the

cyclic oxidation resistance based on specific weight change data. Hot corrosion resistance of the low-and/or no-cobalt Udimet 700 alloys was also investigated. Results by Deadmore (Ref 19) from tests using NaCl-doped flames in a Mach 0.3 burner rig indicate that corrosion resistance increases with decreasing cobalt content. Photographs of exposed specimens are shown in Fig. 9, where the improved corrosion resistance for the lower cobalt concentrations is evident.

Fig. 8 Effect of cobalt on cyclic oxidation resistance of Udimet 700 at 1100 °C (2010 °F) and 1 h/cycle

Fig. 9 Effect of cobalt on hot corrosion; modified Udimet 700, 170 1-h cycles at 900 °C (1650 °F), with 0.5 ppm by weight Na as NaCl, Mach 0.5

In contrast, Zaplatynsky (Ref 20) found that the alloys with an aluminide coating exhibited improved oxidation resistance with increasing cobalt content based on a weight loss criteria during testing in the March 0.3 burner rig. Leis *et al.* (Ref 21), of the Battelle-Columbus Laboratories, investigated the creep fatigue behavior of low-cobalt P/M and CW Udimet 700 alloys and saw no correlation between fatigue resistance and cobalt content. It is concluded that an alloy based on Udimet 700 in which nickel has been substituted for all the cobalt is a viable superalloy for use in turbine applications. This statement applies to both the cast plus wrought and the hot isostatically pressed prealloyed powder processed alloys. Jarrett *et al.* (Ref 16) had previously reported that the alloy, when given a different heat treatment, might also qualify for use in turbine blades. It is suggested that this alloy be considered for future use in aerospace and land-based turbine applications.

Cobalt and Tantalum in MAR-M 247. MAR-M 247, an advanced nickel-base superalloy used in polycrystalline, directionally solidified, and single-crystal form, contains nominally 10 wt% Co and 3 wt% Ta. The effects of removing cobalt from MAR-M 247 have been investigated as part of a cooperative program involving TRW Inc., Teledyne CAE, Case Western Reserve University, and NASA Lewis. The potential industrial application was related to an integral, cast rotor. Therefore, the casting mold and pouring temperatures were selected by Teledyne CAE to simulate blade and hub conditions. Major findings by McLaughlin (Ref 22) of Teledyne and Kortovich (Ref 23) of TRW are summarized in Table 9. A parallel in-depth study on the effects of cobalt on the mechanical properties of MAR-M 247 was undertaken by Nathal (Ref 24). This study explored the mechanisms associated with the effects of cobalt content on the mechanical properties of polycrystalline materials. Nathal postulated that a reduction in γ' weight fraction and carbide formation as a grain-boundary film were responsible for the deleterious effects on creep-rupture properties. It was proposed that reducing the carbon level in the 5% Co alloy may result in an alloy with properties comparable to MAR-M 247, while conserving 50% of the cobalt normally used in this alloy. Nathal also showed that, based on weight change data, the removal of cobalt from MAR-M 247 improves the cyclic oxidation resistance of this alloy at 1100 °C (2010 °F). As in Udimet 700 testing, hot corrosion testing of alloys based on MAR-M 247 chemistry revealed that reducing cobalt also improved corrosion resistance (Ref 19).

Table 9 Effects of removing cobalt from MAR-M 247 blade and hub

Property or characteristic item	Result	
	Blade	Hub
Yield strength	Slight decrease	Slight decrease
Ultimate tensile strength	Decrease	Decrease
Tensile ductility	Decrease	Slight decrease
Stress-rupture life	Decrease	Decrease
Oxidation resistance	No change	No change
Thermal shock	No change	No change
Fracture mode		
Tensile	From transcolony	To intercolony

Nathal *et al.* (Ref 25) further showed that in single-crystal form, removing cobalt from MAR-M 247 appears to increase rupture life and decrease creep rate, trends opposite to those observed for the polycrystalline material. The single-crystal findings by Nathal supported previous results reported by Strangman *et al.* (Ref 26) in which 0% Co levels in single-crystal alloys had longer rupture lives than the 10% cobalt MAR-M 247 single crystals. However, a 5% Co level was required for alloy stability with respect to the formation of the μ phase, a topologically close-packed, hard compound.

Nathal and Ebert (Ref 27) studied the influence of composition on the tensile and creep strength of [001]-oriented nickel-base superalloy single crystals at temperatures near 1000 °C (1830 °F). Cobalt, tantalum, and tungsten concentrations were varied according to a matrix of compositions based on the single-crystal version of MAR-M 247. For alloys with the

baseline refractory metal level of 3 wt% Ta and 10 wt% W, decreasing the cobalt level from 10 to 0 wt% resulted in increased tensile and creep strength. Substitution of 2 wt% W for 3 wt% Ta resulted in decreased creep life at high stresses, but improved creep life at low stresses. Substitution of nickel for tantalum caused large reductions in tensile strength and creep resistance and corresponding increases in ductility. For these alloys with low tantalum plus tungsten totals, strength was independent of the cobalt level. Figures 10 and 11 show the yield stress and creep-rupture properties of the reduced-cobalt and reduced-tantalum alloys. The results of the extensive studies of Nathal and Ebert on microstructure and mechanical properties are summarized in the following paragraphs.

Fig. 10 The 0.2% yield stress at 1000 °C (1830 °F) for single-crystal MAR-M 247 alloys

Fig. 11 Rupture lives of single-crystal MAR-M 247 alloys at 1000 °C (1830 °F) and 148 MPa (22 ksi)

The removal of tantalum and tungsten from the baseline 3Ta-10W alloys to form the 0Ta-9W alloys caused large reductions in γ' solvus temperature and γ' volume fraction. The substitution of tungsten for tantalum to form the 0Ta-12W alloys resulted in intermediate reductions in solvus temperature and volume fraction. The amount of γ' was independent of the cobalt level, although the γ' solvus temperature increased significantly as the cobalt content was reduced from 10 to 0%. The partitioning of elements between the γ and γ' phases did not vary appreciably as the alloy composition varied. Tantalum and titanium partitioned almost totally to γ' ; aluminum and tungsten partitioned preferentially to γ' ; and cobalt, chromium, and molybdenum partitioned preferentially to γ .

The γ' lattice parameter was independent of the cobalt content, but increased as the total refractory metal level increased. At the 0% Co level, the 3Ta-10W alloy exhibited a room-temperature lattice mismatch, where the difference was -0.0037 and the 0Ta-12W alloy exhibited a difference of -0.002. The 0Ta-9W alloys and all alloys with 5 and 10% Co possessed mismatch values below the detection limit.

For the alloys with γ' that remained coherent during aging, the unstressed γ' coarsening rate increased as the cobalt level was reduced from 10 to 0%. The alloys with a high lattice mismatch possessed a γ' that became semicoherent during aging and exhibited anomalously low coarsening rates.

Oriented γ' coarsening, which resulted in lamellae perpendicular to the applied stress, was very prominent during creep. Alloys with higher magnitudes of lattice mismatch exhibited faster directional coarsening rates and a finer spacing of misfit dislocations at the γ/γ' interfaces.

The substitution of nickel for cobalt caused large increases in creep resistance for alloys with high tantalum plus tungsten totals. This was consistent with an increase in γ/γ' lattice mismatch. High values of lattice mismatch resulted in a finer dislocation network at the γ/γ' interface, providing a more effective barrier for dislocation motion. The substitution of nickel for tantalum and tungsten to form the 0Ta-9W alloys caused large reductions in creep resistance, which were related to the decreases in γ' volume fraction, γ/γ' mismatch, and solid-solution hardening. The substitution of tungsten for tantalum to form the 0Ta-12W alloys resulted in a decrease in creep resistance at high stresses and an increase in creep strength at low stresses. This cross-over in creep resistance between the 3Ta-10W and 0Ta-12W alloys was not easily explained. The decreased creep life of the 0Ta-12W alloys at high stresses was attributed to the slight decreases in γ' volume fraction and γ/γ' mismatch, although the reason that tungsten appears to be a more effective solid-solution strengthener at low stresses remains unclear.

Decreases in the cobalt level from 10 to 0% caused significant increases in the 1000 °C (1830 °F) yield and ultimate tensile strengths of the 3Ta-10W alloys, but cobalt had much less effect on alloys with other refractory metals contents. The influence of cobalt on the strength of the 3Ta-10W alloys was attributed to the coherency strain hardening associated with the increased lattice mismatch as the cobalt level decreased. The reduction of tantalum and tungsten content to form the 0Ta-9W alloys caused large reductions in tensile strength, and the substitution of tungsten for tantalum caused intermediate decreases in strength. These changes in tensile strength with refractory metal levels were related to the increases in γ' volume fraction and solid-solution hardening, which resulted from high tantalum plus tungsten totals.

Based on these various studies, it appears that reducing the cobalt content by 50% in MAR-M 247 may be feasible in the event of a cobalt shortage and tungsten may be used as a substitute for a significant amount of tantalum in this alloy.

Tantalum in B-1900+Hf. The alloy B-1900+Hf containing 10 wt% Co and 4 wt% Ta is a high-strength, nickel-base superalloy used in turbine blade applications. Kortovich (Ref 28) conducted some independent studies of the role of tantalum on mechanical properties and microstructure of B-1900+Hf. His results indicated that tensile strength decreased with decreasing tantalum content upon testing at room temperature and at 760 °C (1400 °F). Stress-rupture testing at 760 °C/650 MPa (1400 °F/95 ksi) indicated that the rupture life increased with decreasing tantalum content, while at 980 °C/200 MPa (1795 °F/30 ksi), rupture exhibited a maximum at a 50% reduction in the normal tantalum content. TRW stress-rupture results and tensile results at 769 °C (1400 °F) are shown in Fig. 12.

Fig. 12 Effect of tantalum on mechanical properties of B-1900+Hf at 760 °C (1400 °F). (a) Rupture life at 648 MPa (94 ksi). (b) Tensile strength

Janowski (Ref 29) studied the microstructure of B-1900+Hf alloys tested by Kortovich. Figure 13 shows the γ'/γ partitioning ratios for the various tantalum levels. The partitioning ratios of cobalt, chromium, and nickel are constant with tantalum variations, consistent with MAR-M 247 results. In addition, the partitioning ratios for aluminum, molybdenum, and titanium are also independent of tantalum content. However, the hafnium and tantalum partitioning ratios are very sensitive to tantalum content; the partitioning ratios of hafnium and tantalum decrease and increase, respectively, as tantalum is removed from the alloy. The change in the hafnium distribution was postulated to be a

consequence of the increase in available hafnium in the matrix phases as a result of the replacement of part of the hafnium contained in the metal carbides (MCs) by tantalum. Further work will be required to determine whether an alloy with reduced-tantalum content will be a viable substitute for B-1900+Hf.

Fig. 13 Various γ'/γ phase elemental partitioning ratios for B-1900+Hf alloys as a function of tantalum content

Niobium in Inconel 718. Inconel 718 is used for disks in gas turbine engines and, by weight, is the most widely used superalloy. Ziegler and Wallace (Ref 30) explored a series of Inconel 718 alloys with reduced niobium contents. The alloys had niobium contents of 5.1 (Inconel 718 composition), 3.0, and 1.1 wt%. Substitutions of 3.0% W, 3.0% W plus 0.95% V, and 3 to 5.8% Mo were investigated. Two additional alloys, one containing 3.49% Nb plus 1.10% Ti and a second containing 3.89% Nb and 1.27% Ti, were also studied. Additions of solid-solution elements to a reduced niobium alloy had no significant effect on the properties of the alloys under either process condition. The solution and aged alloys with substitutions of 1.27% Ti at 3.89% Nb had tensile properties similar to those of the original alloy and stress-rupture properties superior to the original alloy. The improved stress-rupture properties were the result of significant precipitation in the alloy, of $\text{Ni}_3\text{Ti}-\gamma'$, which is more stable than γ'' at the elevated temperatures. At lower temperatures this modified alloy benefits from the γ'' strengthening. Much more information is needed to characterize the modified alloy fully, but these initial results suggest that with more precise control and proper processing, the reduced niobium direct-age alloy could substitute for Inconel 718 in high-strength applications.

Advanced Processing

Advanced processing, that is, tailored fabrication and dual-alloy concepts, were to be developed under the COSAM program initially, but very little work in these areas actually occurred because of funding limitations and the focus on substitution. However, industry has independently investigated dual-alloy concepts to improve properties.

A turbine disk is a good candidate for the dual-alloy concept because of its weight and operating characteristics. The rim of a disk operates at higher temperatures than the hub of the disk and requires a nickel-base superalloy for creep resistance. The hub of a disk operates at lower temperatures where fatigue resistance is important, and thus an iron-base superalloy with lower strategic metal content may suffice. The key to this dual-alloy concept is the interface between two alloys of widely different compositions.

Harf (Ref 31) has studied the interface properties of alloy 901 combined with three nickel-base superalloys. His preliminary results showed that the alloys could be joined by the HIP-P/M process and could form a strong, integral bond. Stress-rupture properties of the alloy combinations, with heat treatments for each of the alloys, are shown in Fig. 14. Failure always occurred in alloy 901, indicating the superior strength of the bond. In addition, the rupture lives of the combinations were always equal to or greater than that for alloy 901 alone. These results imply that a dual-alloy concept is viable for enhancing the local properties of gas turbine components and for conserving costly strategic materials. Dual-alloy disks are being investigated for current engines. However, the goal is to achieve optimum properties, not to conserve strategic materials.

Alternate Materials

The third major, COSAM program thrust, alternate materials, has the potential of making a major contribution to the conservation of the four strategic elements studied, including chromium, which is critical to currently used superalloys because of the oxidation/corrosion resistance it provides. The materials being investigated in this part of the program are described below.

Intermetallic Compounds. This effort emphasizes a basic research approach toward understanding the deformation mechanisms that control high-temperature creep, as well as those that control the lack of room-temperature ductility. By necessity, this is a long-term, high-risk effort, but it offers the potential of a high payoff if materials are evolved that permit the conservation of all four currently identified strategic metals.

A research program that focused on the equiatomic iron and nickel aluminides (FeAl and NiAl) as potential alternatives to nickel-base superalloys was conducted in-house at NASA Lewis Research Center and at Dartmouth College, Stanford University, Texas A & M University, and Case Western Reserve University (Ref 32). These binary aluminides have a number of advantages: They exist over a wide range of compositions and have a large solubility for substitutional third-element additions; they have a cubic crystal structure; they have very high melting points (except for FeAl, which has a somewhat lower melting point); they contain inexpensive, readily available elements; and they possess the potential for self-protection in oxidizing environments. Their chief disadvantage is the lack of room-temperature ductility. Cobalt aluminide has been used for comparative purposes because it has unusual mechanical properties and phase equilibria.

Some of the highlights of FeAl are shown in Fig. 15 and 16 (Ref 33, 34). Figure 15 shows the room-temperature tensile elongation of Fe-40Al to be about 1 or 2%. However, 5 to 6% elongation was achieved with the addition of zirconium and

boron. The fracture for alloys without boron was intergranular, while alloys containing boron exhibited transgranular fracture. The creep strength of the Fe-40Al-0.1Zr-0.41B alloy is compared with several commercial iron-nickel-base superalloys in Fig. 16. Results indicate that this alloy has promising properties at elevated temperatures.

Fig. 15 Ductility of Fe-40Al alloys

Fig. 16 Comparison of creep strength of Fe-40Al-0.1Zr-0.41B alloy and commercial iron-nickel-base superalloys

Schulson has described the effects of grain size on the tensile ductility of NiAl (Ref 35). His work was based on the models of Cottrell (Ref 36) and Petch (Ref 37), which stated that the stress required to nucleate microcracks in coarse-grained materials is more than enough to propagate them. In contrast, the stress required to nucleate cracks in fine-grain materials is less than that required to propagate them. In the first case, coarse-grain materials will fail in a brittle manner; in the second, fine-grained material must undergo permanent deformation and work hardening prior to failure. The conclusion is, therefore, that a critical grain size should exist for plastic flow. This does indeed appear to be the case for Ni-49Al at 295 °C (565 °F), as illustrated by the results shown in Fig. 17, where the critical grain size is -20 μm (-785 $\mu\text{in.}$) At lower temperatures, the critical grain size becomes even smaller.

Fig. 17 Effect of grain size (d) on tensile elongation, yield strength (σ_y), and fracture strength (σ_f) of NiAl at 400 °C (750 °F).

Vedula *et al.* (Ref 38) have shown that tantalum-rich precipitates in a Ni-48Al-2Ta alloy can produce an increase in creep strength of nearly two orders of magnitude over the simple, equiatomic, binary NiAl. Dislocations interacting with the precipitates during creep testing are shown in Fig. 18. This alloy is comparable to some nickel-base superalloys at 1025 °C (1875 °F). Intermetallic compounds are currently under extensive investigation by NASA, the U.S. Department of Defense, the U.S. Department of Energy, industry, and universities, both as monolithic materials and as matrices for composites.

Fig. 18 Transmission electron micrograph of NiAl-2 at. % Ta specimen deformed in hot compression at 1300 K to about 7% strain

Iron-Base Alloys. With the successful development of high-strength nickel-base superalloys (and to some extent cobalt-base superalloys) over the last 30 years, there has been little recent interest in developing iron-base alloys for the higher-temperature gas turbine engine components. However, with the threat of strategic material supply disruptions or interruptions, iron-base alloys with low strategic metal contents are now attractive as alternative materials for U.S. industrial consideration.

A program was initiated to investigate iron-base superalloys with aligned carbides for further strengthening as potential alternatives to current high strategic element content nickel- and cobalt-base superalloys. This was a joint program involving the University of Connecticut, United Technologies Research Center, and NASA Lewis. The potential of these iron-chromium-manganese-aluminum alloys is shown in Fig. 19, where rupture lives determined by Lemkey and Bailey (Ref 39) compare favorably with other iron-, nickel-, and cobalt-base alloys. Some of these alloys are leading candidates for Stirling engine applications.

Fig. 19 Stress-rupture potential of Fe-20Cr-10Mn-3.2C alloy

Composites. A third area of alternate-materials technology conducted in-house at NASA Lewis sought to determine the potential of silicon carbide reinforced, low strategic element content, iron-base matrix composites. The program focused on understanding matrix/fiber interface compatibility in the service range from 760 to 900 °C (1400 to 1650 °F) for turbine engine components (Ref 40). This concept offers the potential not only of conserving strategic materials, but also of either reducing component weight because of the potential strength of the fibers and their high volume fraction or of maintaining weight and extending service life. The results of this program can be summarized as follows: First, a low-temperature fabrication process, that is, hollow-cathode sputtering, can be used successfully to produce single-filament composites from B₄C-B SiC filaments and iron-base matrix alloys while retaining high fractions of the filament strength. No evidence of filament/matrix reaction due to processing was observed. Second, single-fiber composites of B₄C-B and SiC filament-reinforced iron-base alloys have stress-rupture strengths at 870 °C (1600 °F) that are superior to those of the strongest superalloys. The 1000-h rupture strength projected for a 50 vol% B₄C-B filament reinforced iron-base alloy composite at 870 °C (1600 °F) is 455 MPa (66 ksi), which represents a 30% increase in strength over a single-crystal CMSX-2. Much more impressive, however, is the 1000-h rupture strength-to-density ratio at 870 °C (1600 °F) projected for the 50 vol% fiber content B₄C-B iron-base alloy composite. This is twice that of CMSX-2, as shown in Fig. 20. Finally, the potential for B₄C-B and SiC filament reinforced iron-base alloy composites for use at intermediate temperatures appears promising if similar processing technologies can be developed for multi-ply composites. The successful result for the development of this technology for turbine components would be the reduction of turbine blade weight. A 40% weight reduction could be obtained in a composite blade using this material, as well as increased blade

life. In addition, with a 50 vol% fiber content, a significant savings in strategic materials would be achieved, compared to nickel-base superalloys.

Fig. 20 Ratio of stress rupture to density for uncoated and coated filaments compared to that of CMSX-2 at 870 °C (1600 °F)

Strategic Materials Availability and Supply

Joseph R. Stephens, National Aeronautics and Space Administration, Lewis Research Center

COSAM Program Results

The COSAM program began in 1980 and continued through 1983. Because of the drop in the cost of cobalt, niobium, and tantalum, and the lessening of any immediate threat of a strategic materials shortage, funding for the program was terminated in 1984. However, research initiated under the COSAM program continues at this writing (funded under other NASA programs) because of the technical promise shown in certain areas, especially that of alternate materials.

Comparing the results that were achieved in the short time that the COSAM program existed with the initial objectives stated earlier in the section "COSAM Program Approach," it is evident that a significant technology bank has been established in the area of a substitution for strategic materials in nickel-base superalloys. This is especially true for cobalt, where knowledge of the physical metallurgy of low- and no-cobalt alloys was characterized in terms of composition microstructure, heat treatment, and thermomechanical processing. Mechanical and environmental properties were described in detail. A similar conclusion for tantalum substitution can also be reached, while niobium substitution was much less clearly defined.

The transfer of this technology to flight hardware must overcome significant barriers between laboratory feasibility and deployment, as discussed by Stephens and Tien (Ref 41). A commitment of both time and money is required to overcome these barriers in the course of the acquisition process, as shown in Fig. 21. Experience in the aircraft engine industry has shown that a 10-year period of development for a new material or concept to reach application, with a minimal expenditure of \$1 million per year, is not uncommon. Because a strategic materials shortage is currently not a threat to aircraft engine producers, such a commitment to move one or more of the lower strategic metal content alloys into flight operation will not in all probability be forth-coming.

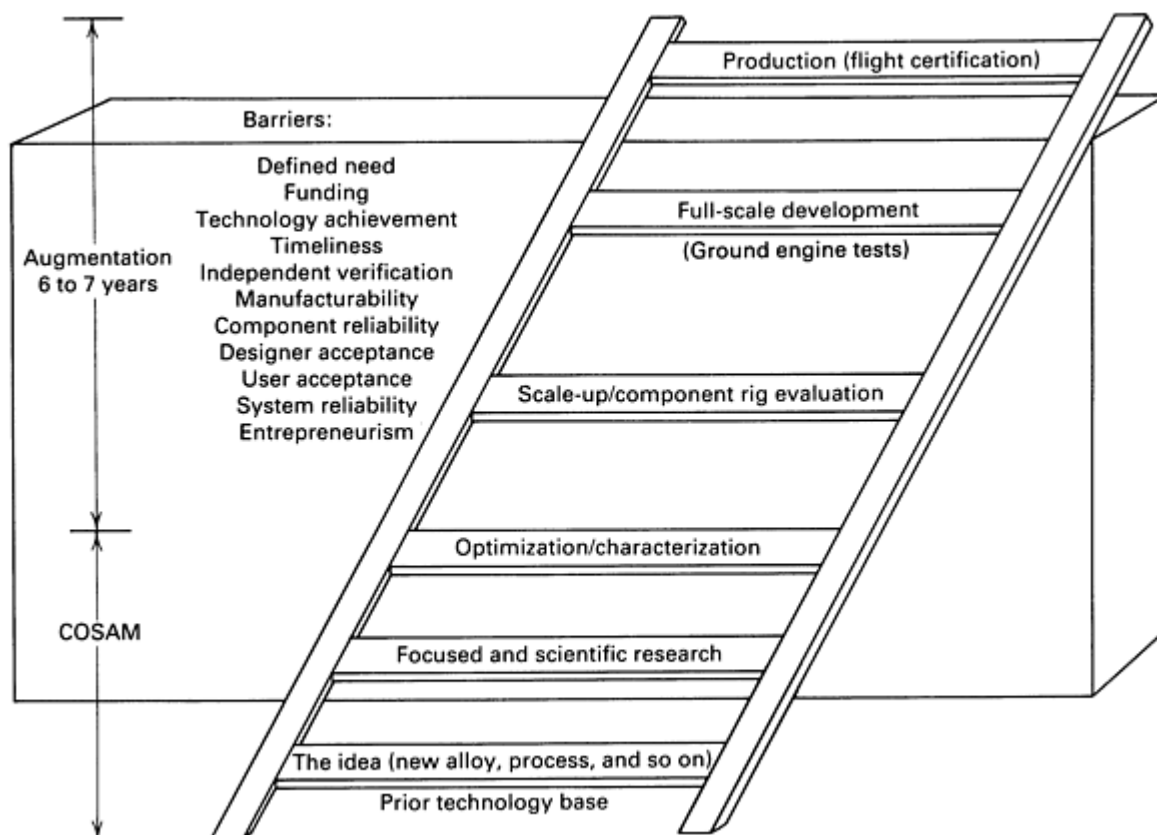

Fig. 21 Technology transfer ladder for strategic material substitution

Because the COSAM program was not carried to fruition, it cannot be claimed that a reduced dependence on potentially unreliable foreign sources was achieved. However, the on-the-shelf knowledge that was gained may contribute to a reduced impact of future supply or cost-derived disruptions.

The objective of reducing costs and optimizing the performance of aircraft engines may well be realized in future advanced aircraft for which lightweight, high-temperature materials are of utmost importance. The continuing alternate materials research on the aluminades and metal matrix and, more recently, intermetallic matrix composites may well lead to improved engines for such vehicles as hypersonic, supersonic, and subsonic transport aircraft. Because of the technical requirements of such aircraft, materials with low or no strategic metal content that have the potential for meeting these needs may overcome the transfer barriers from research to flight hardware if their advantages can be realized and their disadvantages overcome. In addition, potential terrestrial applications for the heater head of experimental automotive Stirling engines (Ref 42) represent a spin-off of research on the iron-base alloys.

Strategic Materials Availability and Supply

Joseph R. Stephens, National Aeronautics and Space Administration, Lewis Research Center

Appendix: Manganese Availability

As discussed previously under the section "Strategic Materials" in this article, manganese falls under the first category, that of most strategic, of the three categories of the 18 metals examined by Stalker *et al.* (Ref 6). Manganese is essential for the production of virtually all steels, and steelmaking constitutes its principal use. It is primarily used to counteract the adverse effects of sulfur and prevent hot shortness or brittleness, which otherwise would develop in steels that contain sulfur. In addition, manganese is used as a deoxidizer to inhibit the formation of grain-boundary carbides, and to impart increased strength, toughness, hardness, and hardenability to steels. Manganese is also used for similar reasons in the production of iron castings. It is used as an alloying element in aluminum, magnesium, and copper. About 90% of the U.S. consumption is for the production of iron and steel. In nonmetallurgical applications, manganese is used in the production of dry cell batteries and as an oxidant or pigmentation agent in various chemicals, paints, and pharmaceutical products.

Strategic Nature. The reliance of the United States on the importation of manganese has been 100% for a number of years. Imports in the form of manganese ore over the 1983 to 1986 time period have been primarily from Gabon (43%) and Brazil (24%). Ferromanganese also constitutes a major source of manganese to the United States and has been imported from South Africa (33%) and France (29%). During the 1983 to 1986 period, the ratio of manganese (imported as ferromanganese) to ore was approximately 1/6. Because the cost of manganese has remained relatively low during the 1980s, a suitable substitute for steelmaking at a similar cost has not been identified. Because most steels have a low manganese content, recycling specifically for manganese recovery is insignificant. Based on these factors, stock-piling seems to be the best hedge against supply disruption for the United States.

Recycling of Iron, Steel, and Superalloys

Thomas A. Phillips, United States Department of the Interior, Bureau of Mines

Introduction

RECYCLING can be simply defined as the use of a material over and over again. The many benefits of recycling include the conservation of natural resources and reductions in energy consumption and in the amount of disposable waste. Recycling within the metals industry involves collecting and reusing scrap metal and metallic wastes to produce new metal or goods such as chemicals. Recycled scrap is a major raw material for the metals industry, supplying up to 100% of the feedstock for some products. Consequently, the scrap metal recycling industry is very important to the economy, providing tens of thousands of jobs across the United States. In addition, the significant quantities of scrap that are exported by the United States improve its balance of trade.

Scrap metal can be divided into two categories, home scrap and purchased scrap, based on its origin. Home scrap is generated within the facility of a producer and recycled directly back into the production process. Purchased scrap, on the other hand, is bought by a dealer or broker and resold to potential users. Purchased scrap is further categorized as either prompt scrap or obsolete scrap. Prompt scrap is scrap generated during fabrication and manufacturing processes. Examples of prompt scrap include turnings, borings, stampings, and even rejected parts. As indicated by the word prompt, this type of scrap can usually be recycled quickly and, in many cases, with minimal processing. Obsolete scrap refers to finished goods that are worn out, broken, or otherwise no longer useful. Automobiles, appliances (white goods), ships, aircraft, machinery, and even cans collected from municipal garbage are example of obsolete scrap.

Home scrap is usually recycled in the form in which it is generated. If the scrap cannot be used as generated, it is usually sold to a scrap dealer and becomes purchased scrap. Companies that deal in scrap can be categorized as either processors or brokers. Processors purchase iron and steel scrap and process, or upgrade, the scrap to meet customer needs. Brokers act as intermediaries, purchasing the scrap from a source and selling it unaltered to a consumer. There are more scrap processors than brokers. However, many processors act as brokers when the scrap is suitable and thus represent both categories.

Although scrap metal is an important raw material for most metal-producing operations, scrap dealers generally operate independently from the metal-producing companies they buy from and sell to. However, a few steel scrap dealers now own steelmaking facilities that utilize the scrap they collect as their primary feedstock material. Scrap metal dealers also tend to specialize in one type of metal, or they have specialized divisions that service the various metals markets. Iron and steel scrap is usually handled separately from stainless steel or superalloy scrap. Therefore, iron and steel recycling is discussed separately from stainless steel and superalloy recycling in this article. Stainless steels and superalloys are discussed together because their technologies and operations are the same; however, they are generally handled at separate facilities, even when the facilities are owned by one company.

This article focuses primarily on the methods and technology used by scrap dealers to recycle purchased scrap. Discussion about the supply and use of this scrap is limited to how processing influences the availability and handling of the scrap. The sections "Recycling Iron and Steel Scrap" and "Recycling Stainless Steel and Superalloy Scrap" in this article describe the size of the scrap recycling industry, scrap use by industry, scrap demand, and the scrap supply.

Recycling of Iron, Steel, and Superalloys

Thomas A. Phillips, United States Department of the Interior, Bureau of Mines

Recycling Iron and Steel Scrap

Scrap iron and steel are the major raw materials in the production of new iron and steel. In 1987, 62×10^6 Mg (68.3×10^6 tons) of iron and steel, or 58% of the total amount produced, was supplied by recycled scrap (Ref 1). Of this amount, about 38% was home scrap, with the remaining 62% consisting of purchased scrap. The delivered value of the purchased

scrap was about \$3.6 billion. An additional 9.4×10^6 Mg (10.4×10^6 tons) of scrap, with a value of about \$967 million, was exported. Thus, the companies that handle this scrap constitute an important industry, one that has a significant impact on the economies of the United States and the world.

Raw steel production consumes about 75% of the purchased iron and steel scrap recycled. An additional 24% is used by foundries that produce cast iron and steel. The remaining 1% is consumed in small quantities for use in ferroalloys, for iron chemical production, and for the precipitation of copper. Of the 24% consumed by foundries, iron foundries take 89%; steel foundries use the remaining 11%.

Scrap Use by Industry

Most recycled iron and steel scrap is used to produce new steel. Three basic steelmaking processes are used today, each utilizing scrap. Most steel, about 60%, is currently produced in a basic oxygen furnace (BOF), which requires about 25 to 30% scrap. In the steelmaking process, scrap acts as a coolant in addition to providing part of the required iron. The metallic charge to a BOF is comprised of hot metal, iron from a blast furnace, and scrap. Oxygen is then blown into the furnace; the oxygen reacts with carbon, impurities, and a small amount of the iron to produce heat, which melts the scrap. Without the scrap, the furnace would have to be cooled by other means. Thus, the use of scrap simplifies the operation of the furnace and improves the overall energy balance by using heat that would otherwise be lost. Forms of cold iron, such as direct-reduced iron (DRI), could be used, but the current cost of DRI favors the use of scrap.

Open-hearth furnaces can be used to produce steel in the same manner as the BOF, but they have been almost totally replaced in the steelmaking process by the BOF process. This is due to the higher thermal efficiency and shorter cycle time offered by the BOF. In 1987, scrap consumed in open-hearth furnaces amounted to only 1×10^6 Mg (1.1×10^6 tons), or about 2% of the total.

Steelmaking capacity using the electric arc furnace (EAF) has increased significantly in the recent past (Fig. 1). In 1950, EAFs accounted for only 6.2% of domestic steel production (Ref 2). By 1987, this had increased to 38%. The EAF can be charged with up to 100% scrap as feedstock; the average charge in 1987 was 99.2% scrap (Ref 1).

Fig. 1 Electric arc furnace being charged with baled scrap. Courtesy of the American Iron and Steel Institute

Electric furnaces have several advantages that have led to their increased use. The first is that an EAF steelmaking facility requires much less capital to build than an integrated steel production facility. Another is that coke is not required, eliminating the cost and environmental problems associated with coke production. In addition, because only scrap melting is taking place, the energy requirement per ton of steel produced is lower for an EAF facility than it is for an integrated steel producer.

Iron and steel foundries that produce cast products are the other major users of iron and steel scrap. Although the primary alternative to scrap is pig iron, current economics favor the use of scrap. Iron and steel foundries used scrap for over 92% of their feedstock in 1987 (Ref 1).

A small market for iron scrap exists for use in the cementation of copper from heap leach solutions. The switch in the copper industry from cementation to solvent extraction and electrowinning technology has substantially reduced this market. Other relatively small markets for iron scrap also exist. One provides iron for the production of chemicals such as pigments; another provides the iron content of some ferroalloys. In total, these minor uses account for about 1% of the iron and steel scrap consumed.

Factors Influencing Scrap Demand

Demand for iron and steel scrap is a function of both the quantity of iron and steel produced and the technology used to produce it. The biggest short-term influence on scrap demand is the general health of the iron and steel industry. Because this industry consumes 99% of the scrap, any change in its production rate affects the demand for scrap.

Changes in steelmaking technology also affect scrap demand. One example of a technology change is the switch from open-hearth furnaces to BOFs at the facilities of integrated steel producers. This switch has reduced the demand for scrap because the BOF uses a lower percentage of scrap in its feedstock. This change in technology is almost complete; very few open-hearth furnaces are still in operation. Additional impact on demand will therefore be negligible.

A second factor influencing the demand for scrap is the steady increase in steel production by mini-mills, which use EAFs to produce steel for specialized markets. These mills also use 98 to 99% scrap as feedstock, which greatly increases the total demand for scrap. Because mini-mills are projected to continue to increase their market share for steel products, the demand for scrap is expected to increase.

Another factor influencing scrap demand is the continuing effort by the iron and steel industries to lower their production costs by investing in newer, more efficient equipment. The adaptation of continuous casting technology is an example of this trend. Current estimates are that 60% of domestic steel production is based on continuous casting. The net result is a more efficient conversion of raw steel to finished product and the generation of less home scrap. Evidence of the trend toward more efficient production technology is the rising percentage of raw steel being converted into finished product. During the past 10 years this percentage has increased from 72 to 87% (Ref 3). To offset the corresponding decrease in home scrap production, steel producers are purchasing additional scrap.

Quality issues also affect demand, especially for high-quality scrap. Manufacturers such as automobile makers are tightening quality standards for their steel purchases. This, in turn, requires tighter control of the quality of the scrap used to produce the steel. High-quality scrap is therefore in short-supply, while there can be surpluses of lower-quality materials such as ferrous scrap from municipal garbage.

Purchased Scrap Supply

As the generation of home scrap has diminished, the demand for purchased scrap per ton of steel produced has increased. The supply of prompt scrap is generally dependent on the production of iron and steel products and is relatively fixed. To satisfy the rising demand, scrap processors are increasing the quantity of obsolete scrap being recycled. Fortunately, a large amount of obsolete scrap has accumulated over the years, and the nation has a substantial scrap inventory.

A problem that might affect the use of some forms of obsolete scrap is the presence of environmentally hazardous components in the scrap products, many of which eventually enter the waste products of the scrap processor. These substances are now regulated as hazardous wastes, which greatly increases disposal costs. Examples of the hazardous materials encountered are cadmium-plated bolts in automobiles, polychlorinated biphenyls in pre-1980 appliances, chromium pigments in paints, and sodium azide in automobile airbags. Under current law, the recycler inherits responsibility for these wastes by processing the scrap. If the cost or liability incurred in the disposal of these wastes

becomes excessive, the processor may stop recycling these products; this not only reduces the supply of obsolete scrap but also increases the negative impact of these hazardous materials.

The Scrap Processor

The scrap processor collects scrap and converts it into a usable form, as defined by the potential customer. A major concern is maximizing the quality of all the scrap collected to increase its total value. Scrap quality depends on many factors, including size, shape, density, chemical composition, and cleanliness.

The scrap processor identifies and stores the scrap by grade. If necessary, the scrap can also be upgraded. Because iron and steel scrap is a relatively low value and high volume commodity, economically viable processing methods are limited. The scrap may have to be separated to remove contaminating items. In addition, large scrap may have to be reduced in size, while loose scrap may have to be compacted.

Collection. Iron and steel scrap is collected--that is, purchased--from a variety of sources, such as salvage yards, automobile wreckers, steel producers, and manufacturers. The value of most scrap is determined by the grade under which it is sold. The Institute of Scrap Recycling Industries (ISRI) has developed specifications for the recognized scrap grades; specifications for some common grades are listed in Table 1. Scrap generators who keep the scrap segregated by grade receive the highest value for their materials because they have eliminated the need for additional processing.

Table 1 Ferrous scrap specifications

ISRI code number	Item	Specification
Basic oxygen, electric furnace, and blast furnace grades		
200	No. 1 heavy melting steel	Wrought iron and/or steel scrap 6.4 mm ($\frac{1}{4}$ in.) and more in thickness. Individual pieces not more than 1.5 × 0.60 m (60 × 24 in.) (charging box size), prepared in a manner to ensure compact charging
203	No. 2 heavy melting steel	Wrought iron and steel scrap, black and galvanized, 3.2 mm ($\frac{1}{8}$ in.) and more in thickness. Charging box size to include material not suitable as No. 1 heavy melting steel. Prepared to ensure compact charging
207	No. 1 busheling	Clean steel scrap, not exceeding 305 mm (12 in.) in any dimensions, including new factory busheling (for example, sheet clippings, stampings, and so on). May not include old auto body and fender stock. Free of metal-coated, limed, vitreous-enameled, and electrical sheet containing over 0.5% Si
208	No. 1 bundles	New black steel sheet scrap, clippings, or skeleton scrap, compressed or hand bundled to charging box size, with a density not less than 1.2 g/cm ³ (75 lb/ft ³). (Hand bundles are tightly secured for handling with a magnet.) May include Stanley balls or mandrel-wound bundles or skeleton reels, tightly secured. May include chemically detinned material. May not include old auto body or fender stock. Free of metal-coated, limed, vitreous-enameled, and electrical sheet containing over 0.5% Si
209	No. 2 bundles	Old black and galvanized steel sheet scrap, hydraulically compressed to charging box size, with a density not less than 1.2 g/cm ³ (75 lb/ft ³). May not include tin- and lead-coated material or vitreous-enameled material
210	Shredded scrap	Homogeneous iron and steel scrap, magnetically separated, originating from automobiles, unprepared No. 1 and No. 2 steel, and miscellaneous baling and sheet scrap. Average density, 1.12 g/cm ³ (70

		lb/ft ³)
213	Shredded tin can for remelting	Tin-coated or tin-free shredded steel cans. May include aluminum tops but must be free of aluminum cans, nonferrous metals except those used in can construction, and nonmetallics of any kind
217	Bundled No. 1 steel	Wrought iron and/or steel scrap 3.2 mm ($\frac{1}{8}$ in.) or more in thickness, compressed to charging box size, with a density not less than 1.2 g/cm ³ (75 lb/ft ³), free of all metal-coated material
221	Shoveling turnings	Clean short steel or wrought iron turnings, drillings, or screw cuttings. May include any such material whether resulting from crushing, raking, or other processes. Free of springy, bushy, tangled, or matted material; also free of lumps, iron borings, nonferrous metals in a free state, grindings, or excessive oil
222	Shoveling turnings and iron borings	Same as shoveling turnings, but including iron borings
223	Iron borings	Clean cast iron or malleable iron borings and drillings. Free of steel turnings, scale, lumps, and excessive oil
Electric furnace casting and foundry grades		
231	Plate and structural steel, 1.5 m (5 ft) and under	Cut structural and plate scrap, 1.5 m (5 ft) and under. Clean, open-hearth steel plates, structural shapes, crop ends, shearings, or broken steel tires. Dimensions not less than 6.4 mm ($\frac{1}{4}$ in.) thick; not more than 1.5 m (5 ft) long and 455 mm (18 in.) wide. Phosphorus or sulfur not over 0.05%
235	Electric furnace bundles	New black steel sheet scrap hydraulically compressed into bundles of size and weight as specified by consumer
236	Cut structural and plate scrap, 0.9 m (3 ft) and under	Clean, open-hearth steel plates, structural shapes, crop ends, shearings, or broken steel tires. Dimensions not less than 6.4 mm ($\frac{1}{4}$ in.) thick; not more than 0.9 m (3 ft) long and 455 mm (18 in.) wide. Phosphorus or sulfur not over 0.05%
242	Foundry steel, 0.6 m (2 ft) and under	Steel scrap 3.2 mm ($\frac{1}{8}$ in.) and more in thickness, not more than 0.6 m (2 ft) long or 455 mm (18 in.) wide. Individual pieces free from attachments. May not include nonferrous metals, cast or malleable iron, cable, or vitreous-enameled or metal-coated material
Specially processed grades to meet consumer requirements		
254	Heavy breakable cast	Cast iron scrap over charging box size or weighing more than 225 kg (500 lb). May include cylinders and driving wheel centers. May include steel that does not exceed 10% of the casting by weight
259	Clean auto cast	Clean auto blocks. Free of all steel parts except camshafts, valves, valve springs, and studs. Free of nonferrous and nonmetallic parts

260	Unstripped motor blocks	Automobile or truck motors from which steel and nonferrous fittings may or may not have been removed. Free from driveshafts and all parts of frames
261	Drop broken machinery cast	Clean, heavy, cast iron machinery scrap that has been broken under a drop. All pieces must be of cupola size, not more than 0.60 × 0.75 m (24 × 30 in.) with no piece more than 70 kg (150 lb) in weight
Railroad ferrous scrap		
24	Melting steel, railroad No. 1	Clean wrought iron or steel scrap, 6.4 mm ($\frac{1}{4}$ in.) and more in thickness, not more than 455 mm (18 in.) wide, and not more than 1.5 m (5 ft) long. May include pipe ends and material 3.2-6.4 mm ($\frac{1}{8}$ - $\frac{1}{4}$ in.) thick, not more than 380 × 380 mm (15 × 15 in.). Individual pieces cut so as to lie reasonably flat in charging box
27	Rail, steel No. 1	Standard section tee rails, original weight of 25 kg/m (50 lb/yd) or more; 3 m (10 ft) long and more. Suitable for rerolling into bars and shapes. Free from bent and twisted rails; frog, switch, and guard rails; or rails with split heads and broken flanges. Continuous-welded rail may be included, provided no weld is more than 230 mm (9 in.) from the end of the piece of rail
28A	Rail, steel No. 2, cropped rail ends	Standard section, original weight of 25 kg/m (50 lb/yd) and more; 455 mm (18 in.) long and less
28B	Rail, steel No. 2, cropped rail ends	Standard section, original weight of 25 kg/m (50 lb/yd) and more; 0.6 m (2 ft) long and less

Source: Ref 4

The collected scrap must be transported to the processing facilities. Because of the relatively low unit value of iron and steel scrap, transportation costs can become significant if the material has to be transported over a great distance. Most scrap processors and brokers can usually bid competitively for scrap within a few hundred miles radius from their facilities, or essentially a 1-day trip by truck. A major exception to this is the export market; the lack of adequate scrap supplies overseas justifies high transportation costs.

Separation and Sorting. The separation of iron and steel scrap from other metals serves two purposes. First, it controls impurities that will alter the properties of the iron or steel produced from the scrap. This is particularly important to foundries because they typically do not use ladle refining technology. The other purpose served by separation is the recovery of additional products that are valuable and can be recycled. Two separation methods commonly used for iron and steel scrap are hand sorting and magnetic separation.

Hand sorting simply involves the removal of components from the scrap by hand; it is therefore a labor-intensive process. Hand sorting is most advantageous when used to remove miscellaneous items from the scrap, or when handling the scrap is unavoidable, such as when loading or off-loading small scrap shipments. Items being sorted are usually identified visually.

Magnetic separation is used when large quantities of iron and steel scrap must be separated from other materials. There are two basic types of magnets, permanent magnets and electromagnets. Permanent magnets are metal alloys that, once magnetized, retain their magnetic properties. An electromagnet uses an electric current passed through copper windings to generate a magnetic field. Permanent magnets are generally less expensive, but electromagnets can be operated at higher magnetic field strengths and can be turned on and off to pick up and drop items.

Electromagnets can be used to separate scrap in stationary piles by picking up the magnetic portion of the material, but they are generally used to move scrap from one point to another. Permanent magnets are used in conjunction with magnetic drum and belt separators, the most common type of separation equipment. In a drum separator, a permanent magnet is located inside a rotating stainless steel shell. Magnetic material on a conveyor passing under the drum is attracted to the magnet and picked up off the conveyor. As the shell turns, it carries the magnetic material out of the magnetic field, allowing it to drop free of the drum to be collected. A magnetic belt separator works on the same principle, except that the magnet is located between two pulleys, around which a continuous belt travels.

Magnetically separated scrap can still contain impurities for several reasons. Nonmagnetic material attached in some way to the magnetic material will be collected. Frequently, a piece of nonmagnetic material caught between the magnet and the magnetic scrap will be carried along with the magnetic material. In addition, other undesired magnetic metals, such as nickel and certain stainless steels, will be collected as well. The most common method of removing these materials is hand sorting because they are usually identifiable by sight. The additional cost of hand sorting is often offset by the value of the nonferrous metal or stainless steel collected.

Size Reduction and Compaction. Large items, such as obsolete ships, railroad cars, truck bodies, structural steel, and large castings, must first be cut to facilitate handling and to enable them to be charged into a furnace. Shears, hand-held torches, and crushers are required for this labor-intensive task. Shears function by forcing a cutter head past a stationary anvil to cut the scrap. Two types of shears are used, alligator and guillotine shears. The alligator shears operate like large scissors with the lower edge fixed. Guillotine shears use hydraulic pressure to force the cutter head down past the anvil. Although cutting an object with a torch is slow and laborious, it is essential for very large items (Fig. 2).

Fig. 2 Large tank being cut down to size with a torch. Courtesy of the Institute of Scrap Recycling Industries, Inc.

Other forms of large scrap can be reduced in size by shredding. Scrap shredders are becoming increasingly important to scrap processors for the recycling of obsolete scrap such as automobiles and white goods. Inside a shredder, steel hammers attached to a drum are rotated past a fixed anvil. As an item is fed into the shredder, it is struck by the hammers and broken, either by direct impact or by being driven against the anvil. Brittle items are shattered, which liberates many of the components previously joined together. An automobile fed into a shredder (Fig. 3) will be reduced to fist-size chunks in less than 1 min. The shredded scrap can then be magnetically separated into magnetic iron and steel fractions and nonmagnetic fractions. Shredded scrap has many desirable qualities, including good density and size uniformity. Other products, such as nonferrous metals and plastic, can be recovered from the nonmagnetic fractions. Automobiles, white goods, and similar items can also be pressed into logs and then sheared to produce a regularly sized product.

Fig. 3 Junked automobile being fed into a shredder. Courtesy of the Institute of Scrap Recycling Industries, Inc.

Loose scrap that has a high surface area and low density is normally compacted by baling or briquetting. Examples of this type of scrap are lathe turnings, punchings, and surplus sheet metal from stampings. Baling involves pressing the scrap into cubic bundles. A baler is a very heavy piece of equipment that uses up to three hydraulic rams to compress the scrap against a fixed wall. In a briquetter, small scrap, such as turnings, is compacted into pockets as it passes between two counterrotating drums. Baled and briquetted scrap has a higher value due to the advantages it gives the furnace operator. In particular, compacted scrap is easier to handle and oxidizes less during melting, which results in better metal recoveries. In addition, for electric furnace operators, the increased density means fewer scrap charges are required per heat.

Detinning. Recycling tin plate scrap generated during the production of steel food and beverage cans requires specialized processors, commonly called detinners. In the detinning process, the scrap is leached with a hot alkaline solution that usually contains sodium hydroxide and sodium nitrate. Metallic tin dissolves quickly, while the tin that has alloyed with the iron (referred to as hardhead) takes additional time. Complete dissolution of the tin is not practical because of the time required; however, the tin content of the steel is reduced to less than 0.03% by this process, which is acceptable for most uses (Ref 5). The steel plate is relatively unaffected by the leach and is washed and baled for recycling. Tin is precipitated from the alkaline solution and recovered by an electrochemical process. Tin cans collected from municipal refuse can also be detinned, but this has not been common practice because the cost of collection and transportation is prohibitive. The presence of aluminum in municipal scrap, especially from bimetallic cans, is often a problem. Aluminum dissolves and consumes reagent, and interferes in subsequent tin recovery steps.

Blending. When levels of impurities are considered to be low, or when the total quantity of contaminated scrap is small, a processor can upgrade the scrap by blending it with scrap of a higher purity. Scrap collected from municipal refuse is frequently blended with higher-grade scrap to dilute the tin and other impurities in the municipal scrap to tolerable levels. Care must be taken when blending scrap to ensure that its final composition is acceptable to the metal producer. If the final impurity levels are too high, the value of all the scrap will be reduced.

Incineration is used by some scrap processors to remove combustible materials. These materials can include an oil or grease coating on the scrap as well as wood or paper mixed in with the scrap. Incineration can also be used to remove volatile metals such as lead and zinc. Rotary furnaces are commonly used by scrap processors.

Recycling of Iron, Steel, and Superalloys

Thomas A. Phillips, United States Department of the Interior, Bureau of Mines

Recycling Stainless Steel and Superalloy Scrap

Stainless steels are iron-base alloys that contain at least 10% Cr. Other metals are frequently added to stainless steel, including nickel, molybdenum, manganese, cobalt, and vanadium. The American Iron and Steel Institute has three general categories of stainless steel, grouped in numbered series.

The 400 series represents straight chromium steel, which contains 10 to 30% chromium, with the balance consisting of iron. A major characteristic of these alloys is that most are magnetic. Stainless steel of the 300 series, on the other hand, is generally nonmagnetic. This series contains nickel and is frequently called 18-8, which signifies the percentages of chromium and nickel in type 304, the most common grade in the series. Additional elements added to stainless steels of this series enable them to attain a wide variety of properties. The 200 series was developed as a low-nickel replacement for the 300 series. In general, the 200 series contains about 4 to 6% Ni, 16 to 20% Cr, and 5 to 16% Mn. The manganese is added to replace nickel. Like the 300 series, the 200 series is nonmagnetic.

Superalloys are those alloys developed for high-temperature service where relatively high stresses (tensile, thermal, vibratory, and shock) are encountered, and where resistance to oxidation is frequently required. These alloys are generally either nickel-iron or nickel- or cobalt-base with varying amounts of additional elements, which can include chromium, molybdenum, niobium, tungsten, titanium, manganese, tantalum, and silicon. Since 1976, the most predominant superalloy has been Inconel 718, with a nominal composition of 52.5% Ni, 19% Cr, 18.5% Fe, 3% Mo, and 5.1% Nb, plus tantalum. Applications of superalloys range from chemically resistant tanks and heat exchanger tubes to components for jet engines.

Scrap Use By Industry

Stainless steel scrap is almost always used to produce more stainless steel. In 1980, 350×10^3 Mg (386,000 tons) of stainless steel was recycled in the United States, supplying about 34% of the stainless steel market (Ref 2). Because the process for making stainless steel is similar to the EAF steelmaking process, the role of scrap is also similar. A wide variety of alloys, including stainless steels and superalloys, are produced by specialty foundries that can use scrap if it matches the composition of the alloy being produced.

In 1986, approximately 25×10^3 Mg (55×10^6 lb) of superalloy scrap was processed, of which 70% was recycled into the same alloy and about 20% was downgraded. The remaining 10% of the recycled scrap was sold to nickel refiners; this is also considered to be a form of downgrading because many valuable elements are refined out of the nickel product and not recovered. This breakdown of the 25×10^3 Mg (55×10^6 lb) includes the 2×10^3 Mg (4.3×10^6 lb) that was exported.

Downgrading refers to the practice of including an alloy in the feedstock of a less critical alloy. For example, a nickel-base superalloy can be blended with other scrap to produce a less critical superalloy or stainless steel. A disadvantage of this practice is that some components of the superalloy can be lost; that is, low levels of the element can be tolerated in the alloy being produced but will have no real function. This represents an effective loss of these valuable metals to the economy.

Superalloys can be roughly divided into two broad categories, air-melted and vacuum-melted alloys. Air melting offers cost advantages for certain alloys. Recycled scrap is acceptable for most air-melted superalloys. Vacuum melting was

developed to prevent the oxidation of alloying elements such as aluminum and titanium. It also allows additional purification of the alloy during production. Product specifications often prohibit the use of recycled feed in vacuum-melted alloys to reduce the chance that detrimental impurities will be included in the final product. This is especially important for critical components such as jet engine parts.

Stainless steels and superalloys are recycled in much the same manner and for the same purpose as iron and steel. The primary difference is that the volume of material recycled is less, while the value per pound is greater. As with iron and steel scrap, stainless steel and superalloy scrap is recycled as either home scrap or purchased scrap. Purchased scrap is handled by either processors or brokers. Processors alter the form of the scrap to that required by the metal producer, while brokers buy and sell scrap without changing its form. Although the companies that recycle iron and steel are similar to those that recycle stainless steel and superalloys, they are usually independent operations.

Scrap Demand

The demand for stainless steel scrap or superalloy scrap is largely a function of the demand for the stainless steel or superalloy itself. A general increase over time is therefore expected as manufacturers increase their use of stainless steels and superalloys to improve product performance. However, the general industrial production rate, which is driven by the overall economy, is the primary factor that influences demand for both the metals and scrap. High demand for stainless steel in 1987 through 1989, following a period of low demand, resulted in a sharply increased demand for stainless steel scrap. Demand is heightened by tight world markets for both chromium and nickel, the use of which can only be replaced by an increased use of scrap. Fortunately, increased demand also raises the value of scrap, which enables more to be recycled. As a major producer and consumer of stainless steel, the United States usually has excess stainless steel scrap, which is exported.

Processing Stainless Steel and Superalloy Scrap

Stainless steels and superalloys are recycled to produce the same metal whenever possible. For example, type 316 stainless steel is recycled to produce more type 316. It is the responsibility of the scrap processor to ensure that the metal producer receives the desired scrap, as needed, and in the desired form.

A scrap processor collects and receives scrap from a number of sources. It is then analyzed and sorted with scrap of the same composition. Mixed scrap must be separated by alloy type. Most of the sorting is done by hand.

Accurate identification of the alloys being recycled is very important because the processor is responsible for the quality of the scrap sold. Scrap that does not meet specifications will be returned by the customer. Superalloy scrap identification utilizes the same procedures as stainless steel scrap identification, except that each piece of superalloy not only has to be identified but also its composition must be certified before it is sold. Scrap that is mixed and impractical to separate will be downgraded.

Collection. Stainless steel and superalloy scrap has a much higher unit value than iron and steel scrap, which reduces the relative impact of transportation costs on the overall recycling cost. Scrap dealers therefore compete for stainless steel and, especially, superalloy scrap on a national and international basis. In addition, scrap may be handled at several locations before it is finally sold for use. Generators of scrap will receive the highest value for their scrap if they keep it separated by alloy type. However, most scrap is mixed and must be separated to be useful.

Separation and Sorting. The separation of the scrap by individual alloy is one of the most important tasks for the scrap processor. Most will handle a wide variety of materials, which makes the ability to identify the scrap a prime concern. Although stainless steel may represent the largest volume of material processed, metals such as superalloys, titanium, nickel alloys, copper, and brasses provide significant income to the processing facility. Identification and sorting utilize a mix of simple and relatively complex procedures, based on any of the physical or chemical properties of the scrap.

Identifying scrap of completely unknown origin usually requires several steps, the choice of which depends on the results of the preceding step (Fig. 4). Initially, physical properties such as color, density, and relative hardness can be used to quickly separate certain classes of material. For example, copper and brass can be identified by their reddish color, while lead can be recognized by both its density and relative softness.

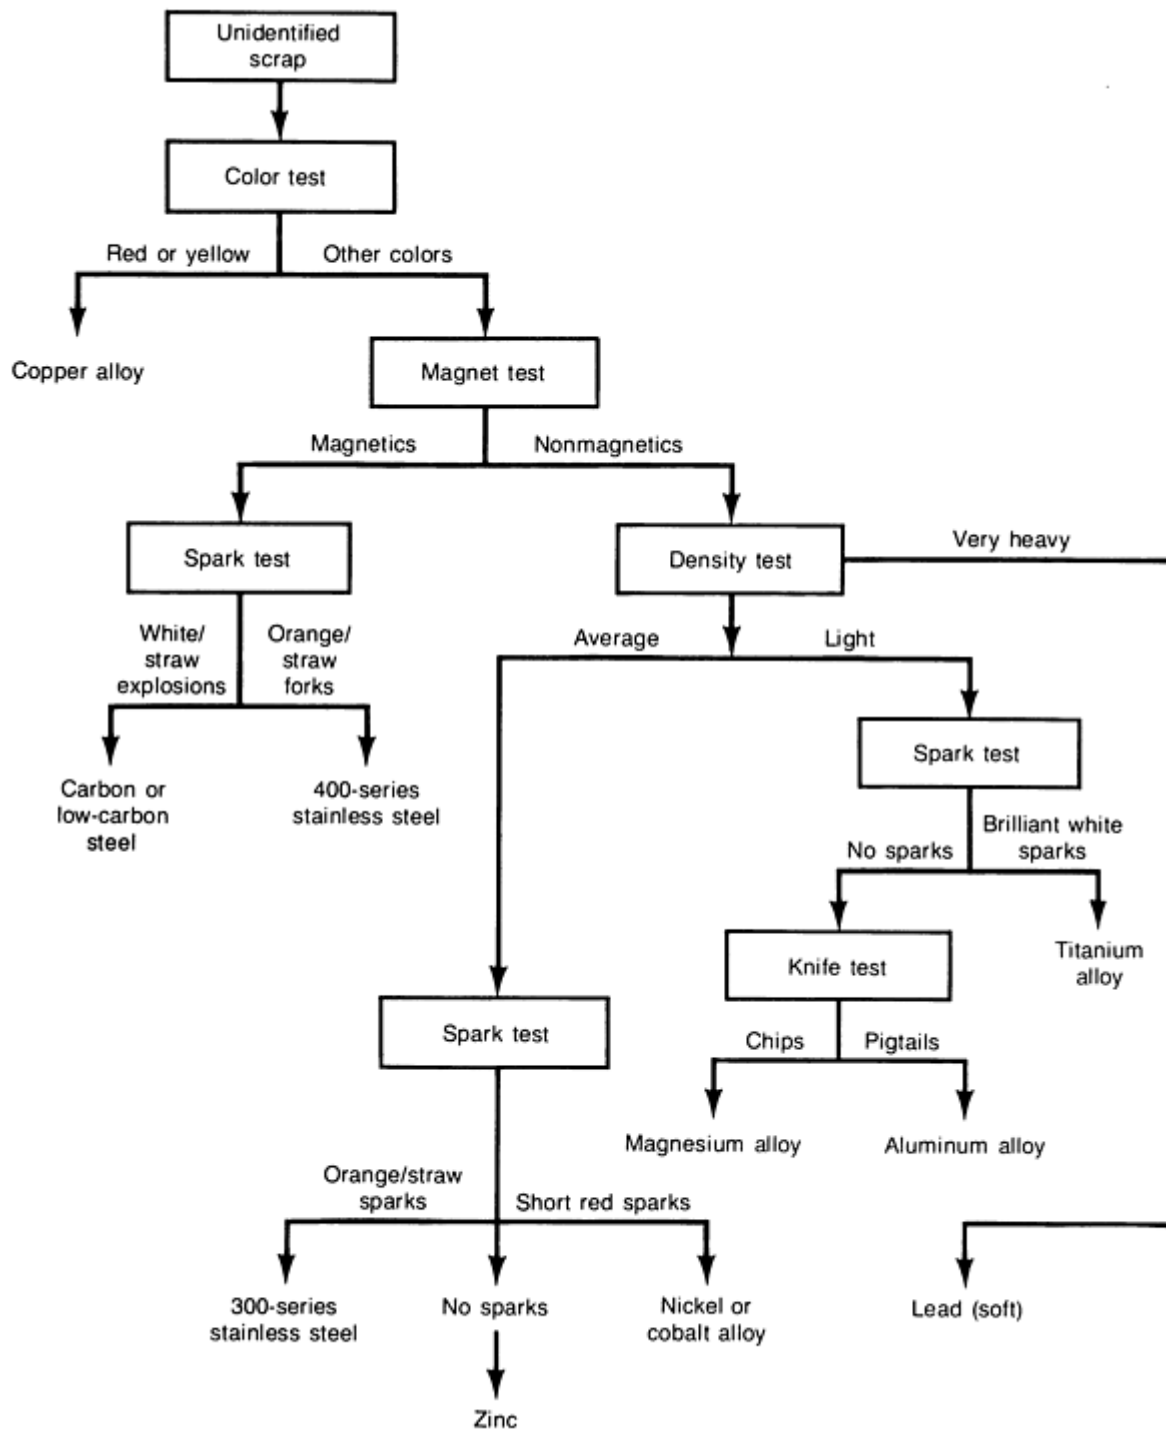

Fig. 4 Simple flowsheet for presorting scrap. Source: Ref 6

Differentiating between alloys of similar composition, such as between grades of stainless steel, is more difficult. For these separations, magnetic testing, spark testing, chemical spot testing, optical and x-ray spectroscopic analysis, thermoelectric analysis, or quantitative chemical analysis is used (Fig. 5).

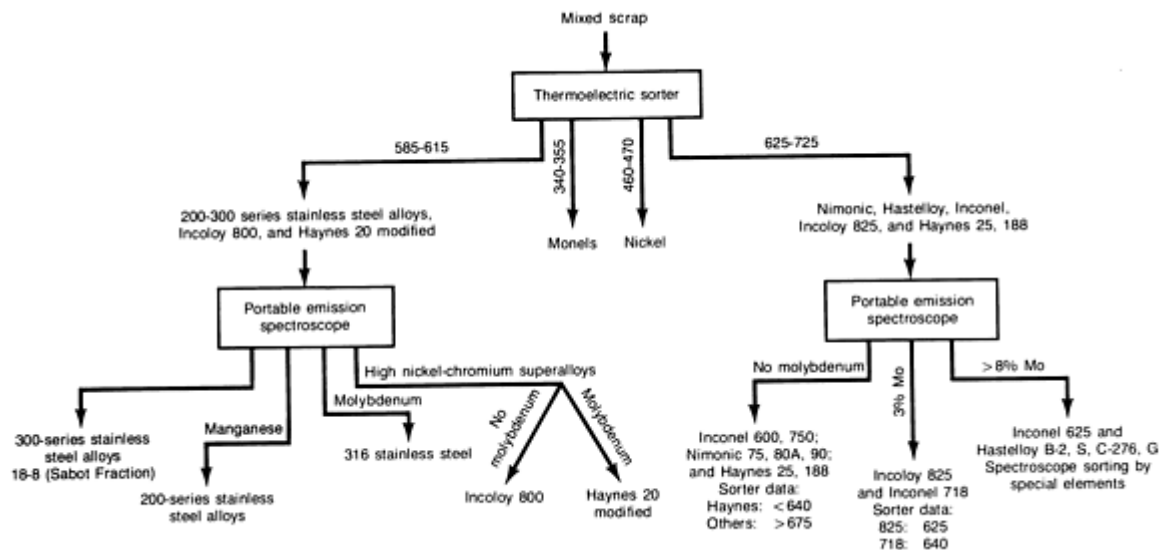

Fig. 5 Instrumental identification technique for sorting stainless steels, nickel alloys, and superalloys. Source: Ref 7

Magnetic testing is a simple test used to determine whether or not a material is ferromagnetic. Iron, nickel, and cobalt are ferromagnetic metals. Low-alloy (mild) and ferritic stainless steels, which include much of the 400 series, are also ferromagnetic. Magnetic testing is therefore a potential means of determining to which series a stainless steel belongs, but it cannot be used to determine the actual alloy within the series.

Spark testing is a scrap identification technique that is indispensable for most processors. A piece of scrap is ground on a high-speed abrasive grinding wheel to produce sparks. A stationary wheel can be used to grind small items, while portable wheels can be used for larger items. The sparks are generated when the abrasive wheel tears off small pieces of the alloy being tested, which are then ignited by the heat generated during this process. The burning particle is seen as the spark. The color and length of the spark are determined by the composition of the piece of metal and the speed at which it burns. Carbides in the alloy will cause secondary bursts, or splitting of the particles. The number and shape of these bursts also help identify the alloy being tested. Metal fragments will tend to stick to the grinding wheel in varying degrees, depending on the alloy being tested. This tendency is also helpful in identifying the alloy. The characteristics of the sparks emitted by several alloys are presented in Table 2.

Table 2 Spark characteristics of various metals and alloys

Material	Spark characteristic
Normal carbon steel	Heavy, dense sparks 455-610 mm (18-24 in.) long that travel completely around the grinding wheel. Sparks are white to straw colored with main burst throughout.
400-series chromium stainless steel	Sparks are not as heavy or dense as those of normal carbon steel. Sparks are 355-455 mm (14-18 in.) long, travel completely around the grinding wheel, and are orange to straw colored, ending with a forked tongue. Preliminary bursts and few main bursts
300-series stainless steel	Sparks are not as heavy or as dense as those of normal carbon steel. Sparks are 305-455 mm (12-18 in.) long, travel completely around the grinding wheel, and are orange to straw colored, ending in a straight line with few if any bursts.
310-series 25-20	The spark stream is thin and 100-150 mm (4-6 in.) long. Sparks are orange to red in color and do not

stainless steel	travel around the grinding wheel; there are no bursts.
Nickel and cobalt high-temperature alloys	The spark stream is thin and about 50 mm (2 in.) long. The sparks are dark red in color and do not travel around the grinding wheel; there are no bursts.

Source: Ref 6

The reliability of spark testing depends on the ability of the test operator to visually differentiate the various spark patterns produced. Skilled personnel are therefore required for dependable results. Test conditions, including lighting conditions, background (preferably dark), and the pressure used to hold the specimen against the wheel, should be uniform. In addition, the wheel must be frequently dressed to remove the metal particles that adhere to it during tests. The use of standards, or samples of known composition, is desirable if positive identification of the alloy is required.

Equipment is available to automatically measure the spectrum given off by the sparks (Fig. 6). The data collected are then compared to known standards by a computer to identify the alloy being tested. The advantages of this system are that a skilled tester is not required and that spectral differences that cannot be detected by eye can be determined by the equipment. However, truly portable equipment has yet to be developed, and the equipment that does exist is not sufficiently proven. As a result, this system is not in general use by the recycling industry.

Fig. 6 Identification of scrap by experimental spark analysis equipment

Chemical spot tests are used as part of a general separation scheme or as the final step in identifying a piece of scrap. The test can be as simple as placing a drop of acid on a clean portion of the testpiece and observing the resulting reaction or lack thereof. A more complicated test involves dissolving a portion of the metal to be identified in a reagent. The resulting solution is then reacted with other reagents and the results observed.

The simplest method of conducting the latter test is to place a few drops of reagent on a clean portion of the surface of the unidentified metal. After an appropriate time has elapsed, the resulting solution is placed on a supporting surface, such as glass, or on a porous surface, such as a piece of filter paper. Other reagents are then mixed with the solution to complete the test. A second approach, an electrographic method, requires sandwiching an electrolyte-impregnated filter cloth between the unidentified metal and an aluminum or platinum cathode. With the piece of scrap acting as the anode, an electric current dissolves a portion of the scrap into the electrolyte. The filter paper can then be removed and tested.

Because chemical spot testing is based on the chemical reactions between the reagents used and the unknown metals being analyzed, test accuracy requires considerable expertise in both the procedures used and the interpretation of the results. The analyzer must be able to differentiate between shades of colors in the solutions or precipitates formed and in speed at which the reaction occurs. It is very important to use standardized reagents to produce uniform results. An example of an identification technique based on chemical testing is shown in Fig. 7.

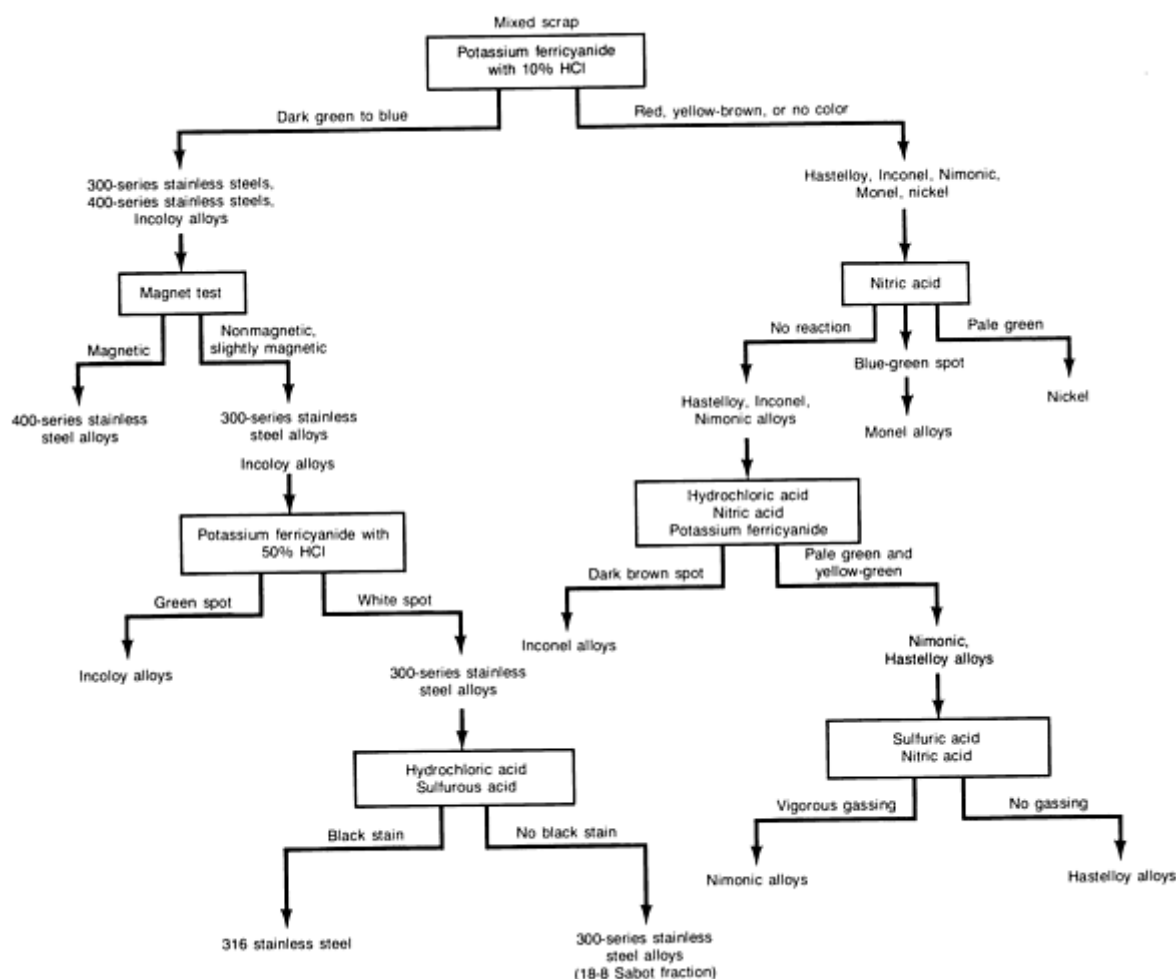

Fig. 7 Chemical test identification technique for nickel-base and stainless steel alloys

Spectroscopic Testing. As the number and complexity of stainless steel and other metallic alloys have increased, the need of the scrap metal processor to more accurately quantify and qualify the metals present has also increased. Spectroscopic analysis has been developed as an analytical tool and is in general use by scrap processors. The basic principle of this analytical technique is that an element, upon being energized, will reemit energy in characteristic wavelengths. Measuring these emissions from the sample and comparing them to a standard permits a quick and accurate analysis of most metals.

In optical spectroscopes, an electrical discharge is used to vaporize a small quantity of metal from the surface of a specimen. The heat provided is sufficient to cause the vaporized metal to luminesce as well. The light emitted is broken down into individual wavelengths, and the individual elements are then identified by the presence of their characteristic wavelengths. Although this type of analysis is very useful in discovering the presence of an element, it is not always accurate in determining the precise quantity that is present.

X-ray spectroscopy (Fig. 8) is another technique for identifying the elements present in an alloy; it is also useful in quantifying the elements present. In principle, a sample is bombarded with x-rays and then radiates back characteristic x-rays that can be detected and used to identify the elements present by comparing the emissions with emissions from

known standards. A potential problem occurs when elements with close atomic numbers are being analyzed because resolution at low concentrations is often difficult, although not always impossible.

Fig. 8 Portable x-ray spectroscope. Source: Ref 7

Available spectroscopic equipment ranges from portable, simple-to-use instruments to highly sophisticated and precise equipment. This equipment is most frequently used by scrap processors to identify and sort scrap with a high alloy content; the unit value of the scrap must be high enough to warrant the use of such equipment. Considerable experience and knowledge of the equipment are required. The results, however, can be obtained relatively quickly, which helps make this type of analytical equipment practical.

Thermoelectric Testing. When two different metals at two different temperatures are in contact, they generate an electric potential known as the Seebeck effect. Thermoelectric devices utilize this effect to identify and sort scrap. These devices contain two probes made of the same metal, one heated and one at ambient temperature. When they contact another piece of metal, the scrap in this case, a potential difference between the two probes is generated and is measured by a voltmeter. The potential difference is characteristic of the metal being tested. Calibration against standards enables various alloys to be identified.

Thermoelectric testing is not possible in all cases because some metals give readings that are too similar to differentiate. Another problem is that the potential difference measured is also affected by the physical condition of the alloy; that is, different voltage readings will be obtained depending on the structure and surface condition of the testpiece. Heat-treated and work-hardened alloys will also produce different results. This kind of testing is generally used in combination with other testing procedures for accurate identification of an alloy.

Quantitative Chemical Analysis. Complete and positive identification of a metal may be required, especially to obtain accurate standards upon which to identify unknown items using less intensive tests. Either standard wet chemical analysis or spectral analysis (or both) can be used for such an analysis. Wet chemical analysis involves dissolving the metal, usually into an acid, and then applying classical chemical analysis techniques to determine the quantity of each element of interest. Optical or x-ray spectroscopy can also be used, either on the sample itself or on solutions derived from it. This type of analysis is often provided by contract laboratories because the equipment and personnel required are costly and specialized.

Size Reduction and Compaction. Large items must be cut to manageable sizes by a processor. The equipment used is the same as that used to size iron and steel scrap. Massive items are cut with torches, while lighter items can be cut with shears. Although shredders are rarely used on stainless steel and superalloy scrap, balers are used to compress suitable scrap in the same manner as for steel scrap.

Degreasing. Some of the metals to be recycled may be coated with oil or grease, such as cutting lubricants or surface-protecting greases, which may have to be removed to facilitate metal identification or to meet product specifications. Solvents such as trichloroethylene are commonly used to remove these contaminants from the scrap. Usually, the scrap to be degreased is loaded into a basket or drum and tumbled or otherwise agitated in the solvent. The oils or grease dissolve into the solvent, and the loaded solvent can be drained away from the metals. To remove any adhering solvent, the clean metal will be washed. The solvent is usually recovered for reuse by selective distillation in an automated solvent regeneration system.

Blending. Many forms of mixed scrap cannot be separated or are too small or otherwise impractical to sort by the techniques described. Much of this, but primarily stainless steel, can still be recycled using a technique known as blending. First, various lots of mixed scrap are extensively sampled and analyzed. The analysis of the entire lot can then be determined using computerized statistics programs. By combining lots of known analysis, a mixture that meets the

specifications of the stainless steel producer can be obtained. Careful sampling and the use of a computer to perform the many requisite calculations are necessary. The scrap processor using this technique must guarantee that the blended scrap will meet the requirements of the customer.

Secondary nickel refining is another recycling method used for scrap that is deemed undesirable in its current form. Examples of the kind of scrap that can be treated by this operation are metals coated with undesirable materials, bimetallic scrap, spills, slags, very oily turnings or grindings, unsortable mixed scrap, or scrap that is physically bound to dissimilar materials. In the alloys processed through such an operation, nickel is the metal of primary economic importance. Other metals such as cobalt, chromium, molybdenum, iron, and copper can also be recovered, but as nickel-base alloys.

The specific technology used by secondary nickel refiners is proprietary. Generally, scrap of known analysis is fed into an electric furnace and melted, and impurities such as oil, grease, and plastic coatings burn off. Volatile metals such as lead or zinc also vaporize and can be collected as baghouse dust. Refractory elements such as chromium or tungsten can be oxidized and collected in the slag by controlling the furnace conditions. The final product will be a nickel (or nickel alloy) pig or shot that is uniform and of known analysis. By carefully analyzing and adjusting the scrap feed-stock in advance, specific alloys that become prime products can be produced.

Metallurgical Wastes. Stainless steel and superalloy producers and product fabricators generate significant quantities of waste materials such as furnace flue dust, mill scale, and grinding swarf. All these materials contain valuable metal constituents, but their analyses will vary depending on the alloy being produced and the technology utilized. These materials are difficult to recycle because they are generally finely divided and often oxidized. They are also often contaminated with a variety of other materials, including slag, grinding abrasives, and other foreign materials.

The technology used to recycle these materials requires that they be pelletized. To facilitate this, the large portions of the wastes must be separated on screens and then ground to a suitable size. Equipment such as a rod mill, a rotating cylinder in which steel rods tumble to grind the material, is commonly used for this step. The fine material is then mixed with a reducing agent (such as coal) and a binder (such as cement). Water is then added, and the mix is fed to a pelletizing disk or drum. A pelletizing disk is a rotating disk that is tilted at an angle. If the water content of the feedstock is correct, the mix will roll on the disk, forming small balls, or pellets. When the pellets reach the desired size, they are automatically discharged from the disk. A pelletizing drum operates in the same way, except that it consists of a tilted rotating cylinder in which the feedstock tumbles until discharged from one end. The formed pellets are then dried.

A few stainless steel producers recycle some of their own waste by feeding the dry pellets directly into the EAF as part of the furnace charge. Once in the furnace the added reductant reacts with the oxidized metals in the pellets to form metals that become part of the stainless steel. Other components of the pellets are incorporated into the furnace slag.

At other facilities, however, the pellets are used to produce a master alloy that can be recycled. Pellets that have simply been dried cannot withstand much handling. Therefore, the dried pellets are indurated, a process that involves heating the pellets in a furnace to a temperature where the individual components fuse together. This hardens the pellets, which are then fed to an EAF where they are melted. Once again, the reductant converts the oxidized metals back to metal. If the feedstock materials used to produce the pellets are blended correctly, a usable alloy is produced, which is then cast into ingots for recycling.

 - statistical process control
- **SQ**
 - structural quality
- **SRGHAZ**
 - subcritically reheated grain-coarsened heat-affected zone
- **SS**
 - Swedish Standard
- **SSC**
 - sulfide stress cracking
- **ST**
 - short transverse
- **STB**
 - Sumitomo top and bottom blowing (process)
- **STEM**
 - scanning transmission electron microscope
- **STQ**
 - solution treated and quenched
- **SWG**
 - steel wire gage
- ***t***
 - thickness; time
- ***T***
 - temperature
- ***T_H***
 - homologous temperature
- ***T_m***
 - melting temperature
- ***T_{nr}***
 - no recrystallization temperature
- **TAPPI**
 - Technical Association of the Pulp and Paper Industry
- **TC**
 - total carbon
- **TCP**
 - topologically close packed
- **TEM**
 - transmission electron microscopy
- **TFS**
 - true fracture stress
- **TH**
 - transformation hardened
- **TIG**
 - tungsten inert gas (welding)
- **TIR**
 - total indicator reading
- **TMCP**
 - thermomechanical controlled processing
- **TME**
 - tempered martensite embrittlement
- **TMP**
 - thermomechanical processing
- **TRIP**
 - transformation induced plasticity
- **tsi**

- tons per square inch
- **TTT**
 - time-temperature transformation
- **UNI**
 - Ente Nazionale Italiano di Unificazione
- **UNS**
 - Unified Numbering System
- **UTS**
 - ultimate tensile strength
- **USSWG**
 - United States steel wire gage
- **V**
 - volt
- **VAD**
 - vacuum arc degassing
- **VADER**
 - vacuum arc double-electrode remelting
- **VAR**
 - vacuum arc remelting
- **V-D**
 - vacuum degassing
- **VIM**
 - vacuum induction melting
- **vol**
 - volume
- **vol%**
 - volume percent
- **W**
 - watt
- **W**
 - width; weight
- **WDS**
 - wavelength dispersive spectroscopy
- **wt%**
 - weight percent
- **WQ**
 - water quenched
- **WRC**
 - Welding Research Council
- **yr**
 - year
- °
 - angular measure; degree
- °C
 - degree Celsius (centigrade)
- °F
 - degree Fahrenheit
- €
 - direction of reaction
- ÷
 - divided by
- =
 - equals
- ≅
 - approximately equals
- ≠
 - not equal to

- \equiv
 - identical with
- $>$
 - greater than
- \gg
 - much greater than
- \geq
 - greater than or equal to
- ∞
 - infinity
- \propto
 - is proportional to; varies as
- \int
 - integral of
- $<$
 - less than
- \ll
 - much less than
- \leq
 - less than or equal to
- \pm
 - maximum deviation
- $-$
 - minus; negative ion charge
- \times
 - diameters (magnification); multiplied by
- \cdot
 - multiplied by
- $/$
 - per
- $\%$
 - percent
- $+$
 - plus; positive ion charge
- $\sqrt{}$
 - square root of
- \sim
 - approximately; similar to
- ∂
 - partial derivative
- Δ
 - change in quantity; an increment; a range
- ϵ
 - strain
- $\dot{\epsilon}$
 - strain rate
- μ
 - friction coefficient; magnetic permeability
- $\mu\text{in.}$
 - microinch
- μm
 - micron (micrometer)
- μs
 - microsecond
- ν
 - Poisson's ratio
- π

- π (3.141592)
- ρ
 - density
- σ
 - stress
- Σ
 - summation of
- τ
 - shear stress
- Ω
 - ohm

- **Tradenames**
- **AF-56**
 - is a registered tradename of Allison Gas Turbine, Division of General Motors Corporation.
- **AL-6X, AL-6XN, AL 29-4C, AL 29-4-2, AL 904L, AL 2205, ALFA IV, E-Brite, 26-1, Sealmet, and 203 EZ**
 - are registered tradenames of Allegheny Ludlum Steel, Division of Allegheny Ludlum Corporation.
- **AM1**
 - is a registered tradename of SNECMA/ONERA.
- **CM 247 LC and CMSX**
 - are registered tradenames of Cannon-Muskegon Corporation.
- **Cronifer**
 - is a registered tradename of Vereinigte Deutsche Metallwerks.
- **Cryogenic Tenelon and Tenelon**
 - are registered tradenames of USS, Division of USX Corporation.
- **Custom 450, Custom 455, Gall-Tough, Pyromet, TrimRite, 7-Mo PLUS, 18-18 PLUS, 20Cb-3, 20Mo-4 and 20Mo-6**
 - are registered tradenames of Carpenter Technology Corporation.
- **Discaloy**
 - is a registered tradename of Westinghouse Electric Corporation.
- **DP3**
 - is a registered tradename of Sumitomo Metal America, Inc.
- **Esshete**
 - is a registered tradename of British Steel Corporation.
- **Ferralium**
 - is a registered tradename of Bonar Langley Alloy Ltd.
- **Hastelloy and Haynes**
 - are registered tradenames of Haynes International, Inc.
- **Incoloy, Inconel, Nimocast, and Nimonic**
 - are registered tradenames of INCO Alloys International, Inc.
- **JS700**
 - is a registered tradename of Jessop Steel Company.
- **MAR-M**
 - is a registered tradename of Martin Marietta Corporation.
- **Monit**
 - is a registered tradename of Uddeholms Aktiebolag.
- **MP (Multiphase)**
 - is a registered tradename of Standard Pressed Steel Company.
- **Nitronic and PH 13-8 Mo**
 - are registered tradenames of Baltimore Specialty Steels Corporation.
- **PH 15-7 MO, 12SR, 15-5 PH, 17-4 PH, 18 SR, and 21-6-9**
 - are registered tradenames of Armco Advanced Materials Corporation.
- **PWA 1484**
 - is a registered tradename of Pratt & Whitney Aircraft.
- **RA85H**
 - is a registered tradename of Rolled Alloys, Inc.
- **René**
 - is a registered tradename of General Electric Company.
- **René 41**
 - is a registered tradename of Allvac Metals Company, a Teledyne Company.
- **RR 2000 and SRR 99**
 - are registered tradenames of Rolls Royce, Inc.
- **Sanicro and 3RE60**

- are registered tradenames of Sandvik, Inc.
 - **Sea-Cure**
 - is a registered tradename of Crucible, Inc.
 - **Stellite**
 - is a registered tradename of Deloro Stellite, Inc.
 - **Udimet**
 - is a registered tradename of Special Metals Corporation.
 - **Unitemp**
 - is a registered tradename of Universal Cyclops Steel Corporation.
 - **Uranus**
 - is a registered tradename of Compagnie des Ateliers et Forges de la Loire.
 - **Vitallium**
 - is a registered tradename of Pfizer Hospital Products Group, Inc.
 - **Waspaloy**
 - is a registered tradename of United Technologies, Inc.
 - **253MA and 254SMO**
 - are registered tradenames of Avesta Stainless, Inc.
-
